Dose Escalation, Not “New Biology,” Can Account for the Efficacy of Stereotactic Body Radiation Therapy With Non-Small Cell Lung Cancer

Stereotactic body radiation therapy (SBRT), also known as stereotactic ablative radiation therapy, is rapidly becoming an accepted practice for the radiation therapy of certain tumors (1), including some lung cancers, liver metastases, brain metastases, recurrent brain tumors, spinal metastases, and kidney and pancreatic tumors. Typically SBRT involves the delivery of 1 or a few large dose fractions of 8-30 Gy per fraction (1). This is a major paradigm shift from the practice of radiation therapy that has developed over the past 90 years when, with relatively large amounts of normal tissues receiving doses close to the prescribed tumor dose, the goal was to maximize tumor response for an acceptable level of normal tissue injury. It is uncontested that fractionation of the radiation dose is superior to single doses in achieving such differential sparing of normal tissue compared with tumor. That fractionation is effective in this situation has been demonstrated in numerous animal models and is concordant with clinical practice over many decades. Stereotactic body radiation therapy can essentially ignore this classic fractionation paradigm because of technological advances in image guidance and treatment delivery techniques that enable the delivery of large doses to tumors with reduced margins with high gradients outside of the target, thereby minimizing doses to relatively large volumes of surrounding normal tissue. For many tumor sites, such as with tumors in the periphery of the lung, this has reduced the concern about unacceptable normal tissue injury and allowed considerable dose escalation.

Concurrently with these clinical developments, laboratory studies have suggested that at high dose fractions (>8-10 Gy) there may be additional biological processes resulting in enhanced tumor cell killing. For example, this has been suggested by studies

from the laboratories of Fuks and Kolesnick, who have reported that high radiation doses produce sphingomyelinase-dependent rapid vascular collapse that markedly enhances the antitumor effect of radiation (2, 3). Second, it has been shown that radiation enhances the antigenicity of tumors (4), although it is not yet clear whether this is greater for large single doses compared with standard fractionation (5). Third, it has been suggested that high doses of radiation such as are delivered by SBRT induce vascular damage over several days that leads secondarily to tumor cell death (6). Any of these factors, colloquially termed a “new biology” (7), could make SBRT more effective than would be predicted from clinical experience with fractionated irradiation. The question addressed here is whether any or all of these processes need to be invoked to explain the remarkable success of SBRT. In particular, for most successful SBRT fractionation schemes the calculated biological effective doses (BEDs) delivered to the tumor are extremely high. So the question becomes this: is the impressive efficacy of SBRT the result of a “new biology” or the result of the high BEDs delivered to the tumor?

A recent publication by Mehta et al (8), who reviewed the available clinical tumor control probability (TCP) data for SBRT and 3-dimensional conformal radiation therapy (3D-CRT) for stage I non-small cell lung cancer (NSCLC), sheds light on the “new biology” versus high BED question. The authors did not address this question, however; rather, they used the clinical data to determine the relationship between TCP and BED and to evaluate the impact of different models on calculated BED values, assuming a tumor radiosensitivity of $\alpha/\beta = 8.6$ Gy and no cellular proliferation. Figure 1 (left) is a replot of the Mehta et al (8) data of TCP against BED for NSCLC, with different symbols for

Conflict of interest: none.

Fig. 1. Tumor control probability (TCP) as a function of biological effective dose (BED) for stage I non-small cell lung cancer. Left: Crude local control rates (≥ 2 years) redrawn from a pooled analysis reported by Mehta et al (8), with different symbols distinguishing 3-dimensional conformal radiation therapy (3D-CRT) and stereotactic body radiation therapy (SBRT) regimens. Right: Weighted mean TCP probabilities calculated from the same data to compensate for the different numbers of patients in each study. Solid lines are TCP predictions for a linear-quadratic-based fit to the available data.

regimens using 3D-CRT and SBRT with either 1 fraction or 3-8 fractions. The reader is reminded that BED is a linear-quadratic model-based estimate of equivalent biological dose that corrects for dose fractionation (9). What can immediately be seen from Figure 1 (left) is that there is a monotonic relationship between TCP and BED for SBRT—a conclusion also recently reached by Ohri et al (10). In other words, the higher the BED, the higher the TCP. More importantly, the data for 3D-CRT also fall on this curve relating TCP to BED for SBRT regimes. We obtain the same conclusion if we bin the studies into BED intervals of 25 Gy (eg, 75-100 Gy, 100-125 Gy, etc) and produce weighted mean TCP probabilities (with SDs) to compensate for the different numbers of patients in each study (Fig. 1, right). In other words, there is no indication from these data that SBRT and 3D-CRT produce different TCP probabilities when adjusted for BED. It is also clear from Figure 1 that, once fractionation has been taken into account through the use of BED, there is no difference in tumor control for single-fraction SBRT compared with multifractionated SBRT. Thus the higher TCPs for SBRT can be fully explained by the much higher tumor BEDs delivered. For NSCLC, then, it follows that there is no need to invoke a “new biology” to explain the high tumor control rates.

This conclusion does not necessarily rule out the existence of a “new biology” at high doses. It does, however, suggest that such new biological processes are unlikely to be contributing significantly to the remarkable success of SBRT, over and above the same primary biological mechanisms that dominate at conventional doses per fraction. The old paradigm, that successful radiation therapy involves putting as much dose into the tumor while depositing as little dose as possible to surrounding normal tissue, seems to remain unchanged. Stereotactic body radiation therapy of NSCLC has taken this to its logical extreme, with dose distributions that are so good that normal tissue sequelae play a much smaller role in determining the maximum tumor dose that can be delivered.

It is important to note that this analysis was specifically of SBRT for early-stage NSCLC, and whether these conclusions apply to other sites has yet to be determined. It is possible that the vascular, stromal, or immunologic effects discussed here could affect SBRT TCP for other tumors; indeed, provocative data on the stimulation of antitumor immunity for melanoma treated with SBRT, thereby leading to a systemic abscopal effect, has recently

been reported (11, 12). Nonetheless, we suggest that the sort of dosimetric analysis described here for NSCLC could similarly resolve the question of “new biology” versus dose for other sites. Hopefully the present analysis will stimulate such comparisons.
