Abstract

In this paper we study stochastic dynamic games with many players; these are a fundamental model for a wide range of economic applications. The standard solution concept for such games is Markov perfect equilibrium (MPE), but it is well known that MPE computation becomes intractable as the number of players increases. We instead consider the notion of stationary equilibrium (SE), where players optimize assuming the empirical distribution of others’ states remains constant at its long run average. We make two main contributions. First, we provide a rigorous justification for using SE. In particular, we provide a parsimonious collection of exogenous conditions over model primitives that guarantee existence of SE, and ensure that an appropriate approximation property to MPE holds, in a general model with possibly unbounded state spaces. Second, we draw a significant connection between the validity of SE, and market structure: under the same conditions that imply SE exist and approximates MPE well, the market becomes fragmented in the limit of many firms. To illustrate this connection, we study in detail a series of dynamic oligopoly examples. These examples show that our conditions enforce a form of “decreasing returns to larger states;” this yields fragmented industries in the SE limit. By contrast, violation of these conditions suggests “increasing returns to larger states” and potential market concentration. In that sense, our work uses a fully dynamic framework to also contribute to a longstanding issue in industrial organization: understanding the determinants of market structure in different industries.

1. Introduction

A common framework to study dynamic economic systems of interacting agents is a stochastic game, as pioneered by Shapley [40]. In a stochastic game agents’ actions directly affect underlying state variables that influence their payoff. The state variables evolve according to a Markov process in discrete time, and players maximize their infinite horizon expected discounted payoff. Stochastic games provide a valuable general framework for a range of economic settings, including dynamic oligopolies—i.e., models of competition among firms over time. In particular, since the introduction of the dynamic oligopoly model of Ericson and Pakes [17], they have been extensively used to study industry dynamics with heterogeneous firms in different applied settings (see [14] for a survey of this literature).

The standard solution concept for stochastic games is Markov perfect equilibrium (MPE) [21], where a player’s equilibrium strategy depends on the current state of all players. MPE presents two significant obstacles as an analytical tool, particularly as the number of players grows large. First is computability: the state space expands in dimension with the number of players, and thus the “curse of dimensionality” kicks in, making computation of MPE infeasible in many problems of practical interest. Second is plausibility: as the number of players grows large, it becomes increasingly difficult to believe that individual players track the exact behavior of the other agents.

To overcome these difficulties, previous research has considered an asymptotic regime in which the number of agents is infinite [30,27]. In this case, individuals take a simpler view of the world: they postulate that fluctuations in the empirical distribution of other players’ states have “averaged out” due to a law of large numbers, and thus they optimize holding the state distribution of other players fixed. Based on this insight, this approach considers an equilibrium concept where agents optimize only with respect to the long run average of the distribution of other players’ states; Hopenhayn [27] refers to this concept as stationary equilibrium (SE), and we adopt his terminology. SE are much simpler to compute and analyze than MPE, making this a useful approach across a wide range of applications. In particular, SE of infinite models have also been extensively used to study industry dynamics (see, for example, [33,35,31,26]).

In this paper, we address two significant questions. First, under what conditions is it justifiable to use SE as a modeling tool? We provide theoretical foundations for the use of SE. In particular, our main results provide a parsimonious collection of exogenous conditions over model primitives that guarantee existence of SE, and ensure that an appropriate approximation property holds. These results provide a rigorous justification for using SE of infinite models to study stochastic games with a large but finite number of players.

The second question we address relates to a longstanding topic of research in industrial organization: when do industries fragment, and when do they concentrate? In a fragmented industry all firms have small market shares, with no single firm or group of firms becoming dominant. By contrast, in a concentrated industry, a few participants that hold a notable market share can exert significant market power. In dynamic oligopoly models in particular, this is a challenging question to answer due to the inherent complexity of MPE. Our second main contribution is to draw a significant connection between the validity of SE, and market structure: under the same conditions that imply SE exist and an appropriate approximation property holds, under all SE the market becomes fragmented in the limit of many firms. In particular, we interpret our con-
ditions over model primitives as enforcement of a form of “decreasing returns to larger states” for an individual firm, that yields fragmented industries in the limit. By contrast, as we discuss, violation of these conditions suggests “increasing returns to larger states” and potential market concentration.

Our main results are described in detail below.

1. **Theoretical foundations for SE: Existence of SE.** We provide natural conditions over model primitives that guarantee existence of SE over unbounded state spaces. This is distinct from prior work on SE, which typically studies models with compact state spaces. Crucially, considering unbounded state spaces allows us to obtain sharp distinctions between increasing and decreasing returns to higher states, and the resulting concentration or fragmentation of an industry.

   In addition, even though SE of a given model may exist over any compact state space, it may fail to exist over an unbounded state space. The reason is that agents may have incentives to grow unboundedly large and in this case the steady-state distribution is not well defined. Hence, a key aspect of our conditions is that they ensure the stability of the stochastic process that describes each agent’s state evolution, and that the resulting steady-state distribution is well defined. In this way, we guarantee the compactness of an appropriately defined “best-response” correspondence. Our conditions also ensure the continuity and convexity of this correspondence, allowing us to use a topological fixed-point approach to prove existence.

2. **Theoretical foundations for SE: Approximating MPE.** We show that the same conditions over model primitives that ensure the existence of SE, imply that SE of infinite models approximate well MPE of models with a finite number of players, as the number of agents increases. An important condition that is required for this approximation result to hold is that the distribution of players’ states in the SE under consideration must possess a light-tail, as originally observed by Weintraub et al. [45] for a sequence of finite games, and in [46] for a limiting infinite model like the one studied in this paper. In a light-tailed equilibrium, no single agent is “dominant;” without such a condition it is not possible for agents’ to rationally ignore the state fluctuations of their dominant competitors.

   Crucially, the light-tail assumption as used by Weintraub et al. [45] and [46] is an endogenous condition on the equilibrium outcome. A central contribution of this work is to develop exogenous conditions over model primitives that ensure the existence of light-tailed SE. In fact, the conditions that guarantee compactness in the existence result ensure that all SE are light-tailed. Thus approximation need not be verified separately; verification of our conditions simultaneously guarantees existence of SE as well as a good approximation to MPE as the number of agents increases.

3. **Market structure in dynamic industries.** Our results provide important insights into market structure in dynamic industries. The literature on dynamic oligopoly models has largely study individual industries in which market outcomes are very sensitive to certain model features and parameters [14]. In contrast, our results provide conditions for which we can predict important features of the equilibrium market structure for a broad range of parameters and specifications.

   In particular, our conditions over model primitives imply that all SE are light-tailed, and therefore, in all SE the industry yields a fragmented market structure and no dominant firms emerge. Moreover, all these SE are valid approximations to MPE. While these conditions cannot pin-down the equilibrium exactly, they guarantee that in all of them the market structure is fragmented. In that sense, our work contributes to the “bounds approach” in the
industrial organization literature pioneered by Sutton [42], which aims to identify broad structural properties in industries that would yield a fragmented or a concentrated market structure. A novelty of our analysis compared to previous work is that it is done in a fully dynamic framework.

To illustrate the connection between our theoretical results and market structure in dynamic industries, we study in detail a collection of three examples in industrial organization. For each of these examples, we demonstrate that our conditions on model primitives that guarantee existence of light-tailed SE can be interpreted as enforcing “decreasing returns to higher states.” Conversely, our analysis of the examples suggests that when these conditions are violated, the resulting models exhibit “increasing returns to higher states,” and SE are not expected to provide accurate approximations or may not even exist. We note that, as emphasized above, unbounded state spaces are necessary to highlight the difference between increasing and decreasing returns to higher states.

The first example we discuss is a quality-ladder dynamic oligopoly model where firms can invest to improve a firm-specific state; e.g., a firm might invest in advertising to improve brand awareness, or invest in R&D to improve product quality [39]. Firms’ single period profits are determined through a monopolistic competition model. Through a limiting construction where the number of firms and market size both scale to infinity, we use our conditions to show that light-tailed SE exist and approximate MPE asymptotically if the single period profit function exhibits diminishing marginal returns to higher quality.

Next, we discuss a model with positive spillovers between firms [24]. Here our conditions impose a form of decreasing returns in the spillover effect that, together with the decreasing returns to investment condition introduced in the previous model, ensure SE exist and provide good approximations to MPE. When the spillover effect is controlled in this way, the market is more likely to fragment.

Finally, we discuss a dynamic oligopoly that incorporates “learning-by-doing,” so that firms become more efficient as they gain experience in the marketplace [20]. In this case, we find that firms’ learning processes must exhibit decreasing returns to scale to ensure existence of light-tailed SE. These conditions are consistent with prior observations in the literature that suggest industries with prominent learning-by-doing effects will tend to concentrate; our results compactly quantify such intuition.

Indeed, in all these examples, our results validate intuition by providing quantifiable insight into market structure. Industries with increasing returns are typically concentrated and dominated by few firms, so SE would not be good approximations. By contrast, our conditions on model primitives delineate a broad range of industries with decreasing returns that become fragmented under SE in the limit, and for which SE provide accurate approximations.

The remainder of the paper is organized as follows. Section 2 describes related literature. Section 3 introduces our stochastic game model, and there we define both MPE and SE. We then preview our results and discuss the motivating examples above in detail in Section 4. In Section 5, we develop exogenous conditions over model primitives that ensure existence of light-tailed SE. In Section 6, we show that under our conditions any light-tailed SE approximates MPE asymptotically. Section 7 revisits the examples in light of the theoretical results provided in the two previous sections. We conclude and discuss future research directions in Section 8. Appendices A–E contain all mathematical proofs as well as important complementary material.
2. Related work

Our work is related to previous literature that studies stationary equilibria or closely-related equilibrium concepts. SE is sometimes called mean field equilibrium because of its relationship to mean field models in physics, where large systems exhibit macroscopic behavior that is considerably more tractable than their microscopic description. (See, e.g., [10] and [38] for related ideas applied to static games.) In the context of stochastic games, SE and related approaches have been proposed under a variety of monikers across economics and engineering; see, e.g., studies of anonymous sequential games [30,7]; dynamic stochastic general equilibrium in macroeconomic modeling [41]; Nash certainty equivalent control [29,28]; mean field games [32]; and dynamic user equilibrium [19]. SE has also been studied in recent works on information percolation models [16], sensitivity analysis in aggregate games [1], coupling of oscillators [48], scaling behavior of markets [11], and in analysis of stochastic games with complementarities [2].

Prior work has considered existence of equilibrium in stochastic games in general, but these are typically established only in restricted classes such as zero-sum games and games of identical interest; see [36] for background. Doraszelski and Satterthwaite [15] and Escobar [18] show existence of MPE for different classes of stochastic games under appropriate concavity assumptions. Our work is particularly related to Jovanovic and Rosenthal [30] and Hopenhayn [27] that consider existence of SE. The former paper considers a model similar to ours but restricts attention to compact sets, while the latter paper is focused on a specific model of oligopoly competition. Adlakha and Johari [2] also consider existence of SE; they focus on games with strategic complementarities, and establish existence using a constructive approach based on lattice theoretic methods. The preceding three papers study a different setting to ours and do not establish an approximation theorem. Several prior papers have considered various notions of approximation properties for SE in specific settings, either with bounded state spaces [22,44,11] or with an exogenous compactness assumption [5], or in linear-quadratic payoff models [28,4].

We briefly discuss here the relation to our own prior work. In our previous conference papers [4,5], we study SE in a less general model of stochastic games than this paper. Though we study existence of SE and an appropriate approximation property, we make an endogenous assumption of compactness; in other words, we assume the model is such that in searching for SE we can restrict attention to a compact set. As a result, those results do not relate model primitives to either validity of SE as an approximation, nor to market structure. By contrast, in this paper, we derive exogenous conditions on model primitives that guarantee compactness, existence of SE, and an appropriate approximation property.

Our paper is also closely related to a paper by Weintraub et al. [46], who study a class of industry dynamic models. They also show a result that depends endogenously on SE: if a given SE satisfies an appropriate light-tail condition, then it approximates MPE well as the number of firms grows. Our paper provides several important contributions with respect to [46]. First, we consider a more general stochastic game model that allows us, for example, to study the models with spillovers and learning-by-doing. We also consider a stronger approximation property. Second, and more importantly, the light-tail condition used to prove the approximation result in Weintraub et al. [46] is a condition over equilibrium outcomes; by contrast, we provide conditions over model primitives that guarantee all SE are light-tailed and hence approximate MPE asymptotically. As a consequence, these conditions also give sharp insight into market structure in our paper. Finally, we provide a novel result pertaining to existence of SE, particularly over unbounded state spaces. We close by noting that Weintraub et al. [46] also consider an analog of SE called “oblivious equilibrium” (OE) in models with finitely many agents. They study the
relation between OE and SE by analyzing the hemicontinuity of the OE correspondence at the point where number of firms becomes infinite.

3. Preliminaries and definitions

In this section we define our general model of a stochastic game, and proceed to define two equilibrium concepts: Markov perfect equilibrium (MPE) and stationary equilibrium (SE). We conclude by defining the asymptotic Markov equilibrium property, which requires that SE approximates MPE well as the number of players grows large.

3.1. Stochastic game model

In this section, we describe our stochastic game model. Compared to standard stochastic games in the literature [40], in our model, every player has an individual state. Players are coupled through their payoffs and state transitions. A stochastic game has the following elements:

Time. The game is played in discrete time. We index time periods by \( t = 0, 1, 2, \ldots \).

Players. There are \( m \) players in the game; we use \( i \) to denote a particular player.

State. The state of player \( i \) at time \( t \) is denoted by \( x_{i,t} \in X \), where \( X \subseteq \mathbb{Z}^d \) is a subset of the \( d \)-dimensional integer lattice. We use \( x_t \) to denote the state of all players at time \( t \) and \( x_{-i,t} \) to denote the state of all players except player \( i \) at time \( t \).

Action. The action taken by player \( i \) at time \( t \) is denoted by \( a_{i,t} \in A \), where \( A \subseteq \mathbb{R}^q \) is a subset of the \( q \)-dimensional Euclidean space. We use \( a_t \) to denote the action of all players at time \( t \).

Transition probabilities. The state of a player evolves in a Markov fashion. Formally, let \( h_t = \{x_0, a_0, \ldots, x_{t-1}, a_{t-1}\} \) denote the history up to time \( t \). Conditional on \( h_t \), players’ states at time \( t \) are independent of each other. This assumption implies that random shocks are idiosyncratic, ruling out aggregate random shocks that are common to all players. The assumption is important to derive our asymptotic results. Player \( i \)'s state \( x_{i,t} \) at time \( t \) depends on the past history \( h_t \) only through the state of player \( i \) at time \( t - 1, x_{i,t-1} \); the states of other players at time \( t - 1, x_{-i,t-1} \); and the action taken by player \( i \) at time \( t - 1, a_{i,t-1} \). We represent the distribution of the next state as a transition kernel \( P \), where:

\[
P(x'_{i} \mid x_i, a_i, x_{-i}) = \text{Prob}(x_{i,t+1} = x'_i \mid x_{i,t} = x_i, a_{i,t} = a_i, x_{-i,t} = x_{-i}).
\] (1)

Payoff. In a given time period, if the state of player \( i \) is \( x_i \), the state of other players is \( x_{-i} \), and the action taken by player \( i \) is \( a_i \), then the single period payoff to player \( i \) is \( \pi(x_i, a_i, x_{-i}) \in \mathbb{R} \).

Discount factor. The players discount their future payoff by a discount factor \( 0 < \beta < 1 \). Thus a player \( i \)'s infinite horizon payoff is given by: \( \sum_{t=0}^{\infty} \beta^t \pi(x_{i,t}, a_{i,t}, x_{-i,t}) \).

In a variety of games, coupling between players is independent of the identity of the players. The notion of anonymity captures scenarios where the interaction between players is via aggregate information about the state (e.g., see [30]). Let \( f^{(m)}_{-i,t}(y) \) denote the fraction of players (excluding player \( i \)) that have their state as \( y \) at time \( t \), i.e.:

\[
f^{(m)}_{-i,t}(y) = \frac{1}{m-1} \sum_{j \neq i, \{x_{j,t} = y\}} 1_{\{x_{j,t} = y\}},
\] (2)

\[1\] For indication of how to proceed with compact but not necessarily discrete state spaces, we refer the reader to the recent independent work of Bodoh-Creed [11].
where \( I_{\{x_j,t = y\}} \) is the indicator function that the state of player \( j \) at time \( t \) is \( y \). We refer to \( f^{(m)}_{-i,t} \) as the population state at time \( t \) (from player \( i \)'s point of view).

**Definition 1 (Anonymous stochastic game).** A stochastic game is called an anonymous stochastic game if the payoff function \( \pi(x_{i,t}, a_{i,t}, x_{-i,t}) \) and transition kernel \( P(x'_{i,t} \mid x_{i,t}, a_{i,t}, x_{-i,t}) \) depend on \( x_{-i,t} \) only through \( f^{(m)}_{-i,t} \). In an abuse of notation, we write \( \pi(x_{i,t}, a_{i,t}, f^{(m)}_{-i,t}) \) for the payoff to player \( i \), and \( P(x'_{i,t} \mid x_{i,t}, a_{i,t}, f^{(m)}_{-i,t}) \) for the transition kernel for player \( i \).

For the remainder of the paper, we focus our attention on anonymous stochastic games. For ease of notation, we often drop the subscript \( i \) and \( t \) and denote a generic transition kernel by \( P(\cdot \mid x, a, f) \), and a generic payoff function by \( \pi(x, a, f) \), where \( f \) represents the population state of players other than the player under consideration. Anonymity requires that a firm’s single period payoff and transition kernel depend on the states of other firms via their empirical distribution over the state space, and not on their specific identity. The examples we discuss in the next section satisfy this assumption. Second, in an anonymous stochastic game the functional form of the payoff function is the same, regardless of the number of players \( m \). In that sense, we often interpret the profit function \( \pi(x, a, f) \) as representing a limiting regime in which the number of agents is infinite. In Section 4 we discuss how to derive this limiting profit function in different applications. Moreover, in Appendix B we briefly discuss how our results can be extended to include the case where there is a sequence of payoff functions that depends on the number of agents.

We introduce some additional useful notation. Let \( \mathcal{F} \) be the set of all possible population states on \( \mathcal{X} \):

\[
\mathcal{F} = \left\{ f : \mathcal{X} \rightarrow [0, 1] \mid f(x) \geq 0, \sum_{x \in \mathcal{X}} f(x) = 1 \right\}.
\]

In addition, we let \( \mathcal{F}^{(m)} \) denote the set of all population states in \( \mathcal{F} \) over \( m-1 \) players, i.e.:

\[
\mathcal{F}^{(m)} = \left\{ f \in \mathcal{F} : \text{there exists } x \in \mathcal{X}^{m-1} \text{ with } f(y) = \frac{1}{m-1} \sum_{j} I_{\{x_j = y\}}, \forall y \in \mathcal{X} \right\}.
\]

### 3.2. Markov perfect equilibrium

In studying stochastic games, attention is typically focused on Markov strategies, where the action of a player at each time is a function of only the current state of every player [21,34]. In the context of anonymous stochastic games, a Markov strategy depends on the current state of the player as well as the current population state. Because a player using such a strategy tracks the evolution of the other players, we refer to such strategies in our context as cognizant strategies.

**Definition 2.** Let \( \mathcal{M} \) be the set of cognizant strategies available to a player. That is, \( \mathcal{M} = \{ \mu \mid \mu : \mathcal{X} \times \mathcal{F} \rightarrow \mathcal{A} \} \).

Consider an \( m \)-player anonymous stochastic game. At every time \( t \), player \( i \) chooses an action \( a_{i,t} \) that depends on its current state and on the current population state \( f^{(m)}_{-i,t} \in \mathcal{F}^{(m)} \). Letting \( \mu_i \in \mathcal{M} \) denote the cognizant strategy used by player \( i \), we have \( a_{i,t} = \mu_i(x_{i,t}, f^{(m)}_{-i,t}) \). The next state of player \( i \) is randomly drawn according to the kernel \( P \):
We let \( \mathbf{\mu}(m) \) denote the strategy vector where every player has chosen strategy \( \mu \). Define \( V(m)(x, f \mid \mathbf{\mu}'(m^{-1})) \) to be the expected net present value for a player with initial state \( x \), and with initial population state \( f \in \mathcal{F}(m) \), given that the player follows a strategy \( \mu' \) and every other player follows the strategy \( \mu \). In particular, we have

\[
V(m)(x, f \mid \mathbf{\mu}'(m^{-1})) \triangleq \mathbb{E} \left[ \sum_{t=0}^{\infty} \beta^t \pi(x_{i,t}, a_{i,t}, f_{-i,t}^{(m)}) \middle| x_{i,0} = x, f_{-i,0}^{(m)} = f; \, \mu_i = \mu', \, \mathbf{\mu}_{-i} = \mathbf{\mu}(m^{-1}) \right],
\]

(5)

where \( \mathbf{\mu}_{-i} \) denotes the strategies employed by every player except \( i \). Note that the state sequence \( x_{i,t} \) and population state sequence \( f_{-i,t}^{(m)} \) evolve according to the transition dynamics (4).

We focus our attention on a symmetric Markov perfect equilibrium (MPE), where all players use the same cognizant strategy \( \mu \). In an abuse of notation, we write \( V(m)(x, f \mid \mathbf{\mu}(m)) \) to refer to the expected discounted value as given in Eq. (5) when every player follows the same cognizant strategy \( \mu \).

### Definition 3 (Markov perfect equilibrium)

The vector of cognizant strategies \( \mathbf{\mu}(m) \in \mathcal{M} \) is a symmetric Markov perfect equilibrium (MPE) if for all initial states \( x \in \mathcal{X} \) and population states \( f \in \mathcal{F}(m) \) we have \( \sup_{\mathbf{\mu}' \in \mathcal{M}} V(m)(x, f \mid \mathbf{\mu}'(m^{-1})) = V(m)(x, f \mid \mathbf{\mu}(m)) \).

Thus, an MPE is a profile of cognizant strategies that simultaneously maximize the expected discounted payoff for every player, given the strategies of other players.\(^2\) It is a well known fact that computing an MPE for a stochastic game is computationally challenging in general [14]. This is because to find an optimal cognizant strategy, each player needs to track and forecast the exact evolution of the entire population state. In certain scenarios, it might be infeasible to exchange or learn this information at every step because of limited communication capacity between players or limited cognitive ability. Moreover, even if this is possible, the computation of an optimal cognizant strategy is subject to a curse of dimensionality; the state space \( \mathcal{F}(m) \) grows too quickly as the number of agents \( m \) and/or the number of individual states \( \mathcal{X} \) becomes large. As a consequence, computing MPE in practice is only possible in models with few agents and few individual states, severely restricting the set of problems for which this equilibrium concept can be used. In the next subsection, we describe a scheme for approximating MPE that alleviates these difficulties.

#### 3.3. Stationary equilibrium

In a game with a large number of players, we might expect that fluctuations of players’ states “average out” and hence the actual population state remains roughly constant over time. Because the effect of other players on a single player’s payoff and transition probabilities is only via the population state, it is intuitive that, as the number of players increases, a single player

\(^2\) Under the assumptions we make later in this paper, it can be shown that for any vector of cognizant strategies of players other than \( i \), an optimal cognizant strategy always exists for player \( i \).
has negligible effect on the outcome of the game. Based on this intuition, related schemes for approximating MPE have been proposed in different application domains via a solution concept we call stationary equilibrium or SE (see Sections 1 and 2 for references on SE and related work).

We consider a limiting model with an infinite number of agents in which a law of large numbers holds exactly. In an SE of this model, each player optimizes its payoff assuming the population state is fixed at its long-run average. Thus, rather than keep track of the exact population state, a single player’s immediate action depends only on his own current state. We call such players oblivious, and refer to their strategies as oblivious strategies. (This terminology is due to Weintraub et al. [45].) Formally, we let \( \mathcal{M}_O \) denote the set of (stationary, nonrandomized) oblivious strategies, defined as follows.

**Definition 4.** Let \( \mathcal{M}_O \) be the set of oblivious strategies available to a player. That is, \( \mathcal{M}_O = \{ \mu \mid \mu : \mathcal{X} \to \mathcal{A} \} \).

Given a strategy \( \mu \in \mathcal{M}_O \), an oblivious player \( i \) takes an action \( a_{i,t} = \mu(x_{i,t}) \) at time \( t \); as before, the next state of the player is randomly distributed according to the transition kernel \( \mathbf{P} \):

\[
x_{i,t+1} \sim \mathbf{P}(: \mid x_{i,t}, \mu(x_{i,t}), f).
\]

Note that because we are considering a limiting model, the player’s state evolves according to a transition kernel with fixed population state \( f \). The interpretation is that a single player conjectures the population state to be \( f \); therefore, in determining a player’s future expected payoff stream, it considers a transition kernel where its own state evolution is affected by the fixed population state \( f \).

We define the oblivious value function \( \tilde{V}(x \mid \mu, f) \) to be the expected net present value for any oblivious player with initial state \( x \), when the long run average population state is \( f \), and the player uses an oblivious strategy \( \mu \). We have

\[
\tilde{V}(x \mid \mu, f) \triangleq \mathbb{E}\left[ \sum_{t=0}^{\infty} \beta^t \pi(x_{i,t}, a_{i,t}, f) \mid x_{i,0} = x; \mu \right].
\]

Note that the state sequence \( x_{i,t} \) is determined by the strategy \( \mu \) according to the dynamics (6), where the population state is fixed at \( f \). We define the optimal oblivious value function \( \tilde{V}^*(x \mid f) \) as

\[
\tilde{V}^*(x \mid f) = \sup_{\mu \in \mathcal{M}_O} \tilde{V}(x \mid \mu, f).
\]

Given a population state \( f \), an oblivious player computes an optimal strategy by maximizing its oblivious value function. Note that because an oblivious player does not track the evolution of the population state and its state evolution depends only on the population state \( f \), if an optimal stationary nonrandomized strategy exists, it will only be a function of the player’s current state—i.e., it must be oblivious even if optimizing over cognizant strategies. We capture this optimization step via the correspondence \( \mathcal{P} \) defined next.

**Definition 5.** The correspondence \( \mathcal{P} : f \to \mathcal{M}_O \) maps a distribution \( f \in \mathcal{F} \) to the set of optimal oblivious strategies for a player. That is, \( \mu \in \mathcal{P}(f) \) if and only if \( \tilde{V}(x \mid \mu, f) = \tilde{V}^*(x \mid f) \) for all \( x \).

Note that \( \mathcal{P} \) maps a distribution to a stationary, nonrandomized oblivious strategy. This is typically without loss of generality, since in most models of interest there always exists such an optimal strategy. We later establish that under our assumptions \( \mathcal{P}(f) \) is nonempty.

Now suppose that the population state is \( f \), and all players are oblivious and play using a stationary strategy \( \mu \). Because of averaging effects, we expect that if the number of agents is
large, then the long run population state should in fact be an invariant distribution of the Markov process on $X$ that describes the evolution of an individual agent, with transition kernel $(6)$. We capture this relationship via the correspondence $\mathcal{D}$, defined next.

**Definition 6.** The correspondence $\mathcal{D} : \mathcal{M}_O \times \mathfrak{F} \rightarrow \mathfrak{F}$ maps the oblivious strategy $\mu$ and population state $f$ to the set of invariant distributions $\mathcal{D}(\mu, f)$ associated with the dynamics $(6)$.

Note that the image of the correspondence $\mathcal{D}$ is empty if the strategy does not result in an invariant distribution. We later establish conditions under which $\mathcal{D}(\mu, f)$ is nonempty. In addition, while we do not impose this restriction a priori, there are many models of interest where $\mathcal{D}$ is actually a function; that is, for all $\mu$ and $f$ the Markov process associated with the dynamics $(6)$ will be ergodic and admit a unique invariant distribution.

We can now define SE. If every agent conjectures that $f$ is the long run population state, then every agent would prefer to play an optimal oblivious strategy $\mu$. On the other hand, if every agent plays $\mu$ and the population state is in fact $f$, then we should expect the long run population state of all players to be an invariant distribution of $(6)$. SE requires a consistency condition: the equilibrium population state $f$ must in fact be an invariant distribution of the dynamics $(6)$ under the strategy $\mu$ and the same population state $f$.

**Definition 7 (Stationary equilibrium).** An oblivious strategy $\mu \in \mathcal{M}_O$ and a distribution $f \in \mathfrak{F}$ constitute a stationary equilibrium (SE) if $\mu \in \mathcal{P}(f)$ and $f \in \mathcal{D}(\mu, f)$.

In the event that the Markov chain induced by $\mu$ and $f$ has multiple invariant distributions, the agents must all conjecture the population state in equilibrium to be $f$. Further, in the event that there exist multiple optimal strategies given $f$, the agents must all choose to play $\mu$. In many models of interest (such as the examples presented in Section 4), both $\mathcal{P}$ and $\mathcal{D}$ are singletons, so such problems do not arise. For later reference, we define the correspondence $\Phi : \mathfrak{F} \rightarrow \mathfrak{F}$ as follows:

$$\Phi(f) = \mathcal{D}(\mathcal{P}(f), f).$$

Observe that with this definition, a pair $(\mu, f)$ is an SE if and only if $f$ is a fixed point of $\Phi$, $f \in \Phi(f)$, such that $\mu \in \mathcal{P}(f)$ and $f \in \mathcal{D}(\mu, f)$.

### 3.4. Approximation

A central goal of this paper is to determine conditions under which SE provides a good approximation to MPE as the number of players grows large. Here we formalize the approximation property of interest, referred to as the asymptotic Markov equilibrium (AME) property. Intuitively, this property requires that an SE strategy is approximately optimal even when compared against Markov strategies, as the number of players grows large.

**Definition 8 (Asymptotic Markov equilibrium).** A stationary equilibrium $(\mu, f)$ possesses the asymptotic Markov equilibrium (AME) property if for all states $x$ and sequences of cognizant strategies $\mu_m \in \mathcal{M}$, we have:

$$\limsup_{m \rightarrow \infty} V^{(m)}(x, f^{(m)} | \mu_m, \mu^{(m-1)}) - V^{(m)}(x, f^{(m)} | \mu^{(m)}) \leq 0,$$

(9)
almost surely, where the initial population state \( f^{(m)} \) is derived by sampling each other player’s initial state independently from the probability mass function \( f \).

Note that \( V^{(m)}(x, f^{(m)} | \mu', \mu^{(m-1)}) \) is the actual value function of a player as defined in Eq. (5), when the player uses a cognizant strategy \( \mu' \) and every other player plays an oblivious strategy \( \mu \). Similarly, \( V^{(m)}(x, f^{(m)} | \mu^{(m)}) \) is the actual value function of a player as defined in Eq. (5) when every player is playing the oblivious strategy \( \mu \). AME requires that the error when using the SE strategy approaches zero almost surely with respect to the randomness in the initial population state. Hence, AME requires that the SE strategy becomes approximately optimal as the number of agents grows, with respect to population states that have nonzero probability of occurrence when sampling individual states according to the invariant distribution.\(^3\) This definition can be shown to be stronger than the definition considered by Weintraub et al. [45], where AME is defined only in expectation with respect to randomness in the initial population state.

Note that MPE requires that agents optimize their net present value starting from any state \((x, f)\). The AME imposes a weaker requirement: agents do not have profitable deviations asymptotically starting from any individual state \( x \), but only from population states that have nonzero probability of occurrence under the invariant distribution. It would not be possible to obtain our approximation result starting from all population states, because SE decisions may be suboptimal for population states that are far from the long run average state. Offsetting this effect is the fact that these states have very low probability of occurrence.

Since SE only approximates MPE in states that have positive probability of occurrence, there may exist MPE which SE does not have the ability to approximate. In particular, SE is not able to approximate MPE in which behavior depends on off-the-equilibrium-path values; for example, this may be the case in tacit collusive equilibria. In this sense, SE can be also understood (at least heuristically) as a mechanism that selects a certain class of MPE.

3.5. Extensions to the basic model

We briefly mention a few extensions for which all our results follow. These extensions are often important in applications, but do not require any significant additional technical arguments.

First, note that players are ex-ante homogeneous in the model considered, in the sense that they share the same model primitives. This is not a particularly consequential choice, and is made primarily for notational convenience; indeed, by an appropriate redefinition of state we can model agent heterogeneity via types. See Appendix A for further details.

Second, in our basic model we assume that a fixed number of players \( m \) participate in the game at every period. An important extension, particularly relevant for dynamic oligopoly models in industrial organization, is to allow players (e.g., firms) to make entry and exit decisions to and from the industry. There are different potential extensions to our basic model that incorporate entry and exit; we present one specification that is relatively straightforward. In particular, we assume there exists a distinct “inactive” state, the state \( x^0 = (0, \ldots, 0) \); firms in state \( x^0 \) do not compete in the market and do not receive payoffs as given by \( \pi(\cdot) \). However, firms in this state can, at every period, decide to enter the market at a pre-determined state \( x^e \in \mathcal{X} \) and become active the next period after paying a deterministic entry cost. In addition, firms in a finite subset

\(^3\) As noted earlier, under the assumptions we make an optimal cognizant strategy can be shown to exist, for any vector of cognizant strategies of the opponents. Therefore the AME property can be equivalently stated as the requirement that for all \( x \): \( \lim_{m \to \infty} \left( \sup_{\mu_m \in \mathcal{M}} V^{(m)}(x, f^{(m)} | \mu_m, \mu^{(m-1)}) - V^{(m)}(x, f^{(m)} | \mu^{(m)}) \right) = 0 \), almost surely.
of states \( \mathcal{E} \subset \mathcal{X} \), \( x^0 \notin \mathcal{E} \), can decide to exit the market and transition to the inactive state \( x^0 \) after receiving a deterministic “sell-off” value. Both the entry cost and sell-off value are assumed to be common knowledge. Entry and exit decisions are binary; therefore, to ensure existence of equilibrium we assume that players maximize payoffs with respect to randomized strategies. It is straightforward to show that all of our results extend to this setting.\(^4\)

Third, note that in the game defined here, players are coupled through their states: both the transition kernel and the payoff depend on the current state of all players. However, in many models of interest the transition kernel and payoff of a player may depend on both the current state and current actions of other players. In particular, the example in Section 4.3 is a model where players are coupled through their actions. All the results of this paper naturally extend to a setting where players may also be coupled through their actions, i.e., where the transition kernel and payoff may depend on the current actions of all players as well; see Appendix A for further details. In the context of this paper, when players are coupled through actions, for technical simplicity we focus on finite action spaces. In this setting, to ensure existence of equilibrium, we assume that players maximize payoffs with respect to randomized strategies. In addition, we briefly discuss how our results could be extended to include continuous action spaces as well (see Appendix A).

4. Preview of results and motivating examples

As discussed in the Introduction, this paper makes two complementary contributions. On one hand, we establish sufficient conditions over model primitives that provide justification for use of SE (in particular, that guarantee existence of SE and the AME property). On the other hand, we demonstrate that our conditions encode an economic dichotomy, broadly, between “increasing” and “decreasing” returns to higher states; the latter corresponds to those models where the industry becomes fragmented under SE in the limit, and SE is an appropriate modeling tool. In this way, our conditions directly provide insight into market structure.

This section is devoted to introducing examples drawn from industrial organization that motivate and illustrate our results.\(^5\) Each example presents the same basic difficulty: in terms of the parameters of the model, where does the boundary lie between those markets where fragmentation might arise, and those markets where concentration might be expected? As suggested by the preceding discussion, we use SE as a tool to inform this market structure question. In each example, we discuss how our technical results yield sharp conditions under which SE exist, the AME property holds, and all SE yield market fragmentation. We also discuss how failure of the conditions would suggest market concentration.

To set the stage, we first briefly preview the approach behind our main technical results (see Sections 5 and 6). The mathematical complexity in our analysis arises due to unbounded state spaces; these are essential if we hope to identify a boundary between fragmentation and concentration in the limit of many firms. Unfortunately, with unbounded state spaces, both existence of SE and the AME property may become difficult to establish. Informally, this is because mass

\(^{4}\) We note that in this model if the entry cost is larger than the sell-off value, there will be no exit observed in an SE. More interesting dynamics can be generated with private random sell-off values; however, this requires further extensions of the model, in particular to include asymmetric information.

\(^{5}\) In a longer version of this paper, we also present two additional applications of our results, to a model of supply chain competition, and a model of consumer learning [3].
in the population state may “escape” to larger states as the number of firms grows; alternatively, firms may choose strategies that lead to unbounded steady state distributions over the state space.

The key condition we require to overcome these hurdles is to ensure that SE have light tails, i.e., limited mass at larger states (in a sense we make precise later). We develop exogenous conditions over model primitives that ensure all SE population states have light tails, and we further show that all light-tailed SE satisfy the AME property (extending a prior result of Weintraub et al. [46]). Light tails ensure that no single dominant agent emerges in the limit of many firms. Note that in market structure terms, this is exactly market fragmentation.

Interpretation of our exogenous conditions reveals exactly the dichotomy introduced above: the conditions enforce a form of “decreasing returns to higher states” in the optimization problem faced by an individual agent, while their failure corresponds roughly to “increasing returns.” Notably, all our results in the examples are simply applications of the same theoretical architecture. As we point out, when the examples below violate the assumptions we require—in particular, in models that exhibit increasing returns to higher states—we also expect that SE will not satisfy the AME property, and indeed, may not exist. Thus despite the fact that we only discuss sufficient conditions for existence and approximation in this paper, the examples suggest that perhaps these sufficient conditions identify a reasonable boundary between those models that admit analysis via SE, and those that do not.

For the rest of this section, we consider stochastic games with \( m \) players in which the state of a player takes values on \( \mathbb{Z}_+ \).

4.1. Dynamic oligopoly models

Dynamic oligopoly models have received significant attention in the recent industrial organization literature (see [14] for a survey). In these models, firms’ states correspond to some variable that affects profitability; for example, the state could represent the firm’s product quality, its current productivity level, or its capacity. Per period profits are based on a static competition game, with heterogeneity among firms determined by their respective quality levels. Firms take actions to improve their quality; in the absence of this investment quality degrades over time.

Such models are extremely broad and capture a wide range of dynamic phenomena in industrial organization. In this context, we address the following important question: under what conditions on the model primitives do we obtain concentration of the market, and under what conditions do we obtain fragmentation? Intuitively, we might expect that firms need to exhibit decreasing returns to their investments to obtain fragmentation. Our technical results yield a simple condition on model primitives that formalizes this intuition: we require that the single stage profit function exhibits decreasing returns to firm quality. In this case SE exist, the AME property holds, and the SE market structure is fragmented in the limit.

We now describe our specific model and our result in more detail.

**States.** For concreteness, here we consider the quality ladder model of Pakes and McGuire [39], where the state \( x_{i,t} \in \mathbb{Z}_+ \) represents the quality of the product produced by firm \( i \) at time \( t \).

**Actions.** Investments improve the state variable over time. At each time \( t \), firm \( i \) invests \( a_{i,t} \in [0, \bar{a}] \) to improve the quality of its product. The action changes the state of the firm in a stochastic fashion as described below.

**Payoffs.** We consider a payoff function derived from price competition under a classic logit demand system. In such a model, there are \( n \) consumers in the market. In period \( t \), consumer \( j \) receives utility \( u_{ij,t} \) from consuming the good produced by firm \( i \) given by: \( u_{ij,t} = \theta_1 \ln(x_{it}+1) + \)
\[ \theta_2 \ln(Y - p_{it}) + v_{ijt}, \] where \( \theta_1, \theta_2 > 0 \), \( Y \) is the consumer’s income, and \( p_{it} \) is the price of the good produced by firm \( i \). Here \( v_{ijt} \) are i.i.d. Gumbel random variables that represent unobserved characteristics for each consumer-good pair.

We assume that there are \( m \) firms that set prices in the spot market. For a constant marginal production cost \( c \), there is a unique Nash equilibrium in pure strategies of the pricing game, denoted \( p^*_t \) [12]. For our limit profit function, we consider an asymptotic regime in which the market size \( n \) and the number of firms \( m \) grow to infinity at the same rate. The limiting profit function corresponds to a logit model of monopolistic competition [9] and is given by

\[ \pi(x, a, f) = \tilde{c}(x + 1)^{\theta_1} - da, \] where \( \tilde{c} \) is a constant that depends on the limit equilibrium price, \( c \), \( \theta_2 \), and \( Y \). Here the second term is the cost of investment, where \( d > 0 \) is the marginal cost per unit investment.

\textbf{Transition dynamics.} We use dynamics similar to those in Pakes and McGuire [39] that have been widely used in dynamic oligopoly models. Compared to that paper, we assume random shocks are idiosyncratic. At each time period, a firm’s investment of \( a \) is successful with probability \( \alpha a \) for some \( \alpha > 0 \), in which case the quality level of its product increases by one level. The parameter \( \alpha \) represents the effectiveness of the investment. The firm’s product depreciates one quality level with probability \( \delta \in (0, 1) \) independently at each time period. Thus a firm’s state decreases by one with probability \( \delta \frac{\delta}{1 + \alpha a} \); it increases by one with probability \( \frac{(1 - \delta)\alpha a}{1 + \alpha a} \) and stays at the same level with probability \( \frac{1 - \delta + \delta \alpha a}{1 + \alpha a} \).

\textbf{Discussion.} Our main result for this model is the following proposition. The proof can be found in Section 7.1.

\textbf{Proposition 1.} Suppose that \( \theta_1 < 1 \). Then there exists an SE for the dynamic oligopoly model, and all SE possess the AME property.

The preceding result has a natural interpretation in terms of increasing and decreasing returns to higher states. Recall that \( \theta_1 \) represents how much consumers value the quality of the products, and hence if \( \theta_1 < 1 \), firms have strictly decreasing marginal returns in their payoff from increasing their own state. This implies that as their state grows, firms have less incentives to invest in improving their own state and ensures that, in equilibrium, the distribution of firms over the state space has a light tail and, therefore, the market structure becomes fragmented in the limit. On the other hand, if \( \theta_1 \geq 1 \), then firms have an increasing marginal gain in their payoff from increasing their own state. Because the marginal cost of investment is constant, firms may continue to invest large amounts to improve their state even at very large states. Thus, a single firm optimization problem may not even induce a stable Markov process, and hence an SE may not exist (and the AME property may fail).

This result matches our intuition for exactly those regimes where SE work well as approximations to equilibria in finite models. In industries with decreasing returns, we expect to see a fragmented structure in the limit. By contrast, in industries with increasing returns, market concentration would likely result in the limit, i.e., a few firms capture most of the demand in the market. This is precisely where the AME property ceases to hold.

\subsection*{4.2. Dynamic oligopoly models with positive spillovers}

In this section, we extend the previous model to account for positive spillovers, or externalities, across firms. Spillovers are commonly observed in industry data and could arise, for example, due to laggard firms imitating leaders’ R&D activities [24]. The main difference from
the preceding model is that now transition dynamics are coupled among the firms: one firm’s state is more likely to increase if other firms are at higher quality levels.

Again, we are led to consider the effect of spillovers on market structure. From a technical standpoint, the main complexity is that firms’ best responses may lead to unbounded distributions over the state space, due to the spillover effect. Thus, in order to ensure existence of SE and the AME property, we need a condition that controls the spillover effect: intuitively, if the spillover effect is not “too strong,” then the dynamics will effectively exhibit decreasing returns. Our results quantify this sufficient condition. As before, in this case, market fragmentation is obtained under SE in the limit of many firms.

To introduce spillovers, we consider a formal model in which the state space, action space, and payoff are identical to the previous section, and we continue to use the same notation. However, we modify the transition kernel to include spillovers, as described below.

**Transition dynamics.** We follow the model of Xu [47], in which transition dynamics depend not only on the action of the firm, but also on the state of its competitors. Formally, let \( s_{i,t}^{(m)} \) be the spillover effect of the population state on player \( i \) at time \( t \), where:

\[
s_{i,t}^{(m)} = \sum_{y \in X} f_{i,t}(y) h_{i,t}(y).
\]

Here \( h_{i,t}(y) \) is a weight function that distinguishes the effect of different states. For example, we use \( h_{i,t}(y) = \zeta(y) \) for some uniformly bounded function \( \zeta(y) \). We define the effective investment of player \( i \) at time \( t \) by:

\[
a_i,t + \gamma s_{i,t}^{(m)} = e_{i,t}.
\]

The constant \( \gamma \) is a spillover coefficient and it captures the effect of industry state on the state transition. A higher value of \( \gamma \) means a higher spillover effect. With an effective investment of \( e \), similar to Section 4.1, a firm’s state increases by one level with probability \( \alpha e \), and finally, as before, the firm’s product depreciates in quality by one level with probability \( \delta \in (0, 1) \) independently at each time period.

**Discussion.** Since the kernel now depends on the population state \( f \) through the spillover effect, even if \( \theta_1 < 1 \), the population state of an agent may grow due to large competitor states. This may lead to a scenario where the image of \( \Phi \) is unbounded, because firms may exhibit unbounded growth. The following proposition provides a simple condition for existence of SE. The proof can be found in Section 7.2.

**Proposition 2.** Suppose that \( \theta_1 < 1 \), and:

\[
\gamma < \frac{\delta}{(1 - \delta)\alpha \sup_{y} \zeta(y)}.
\]

Then there exists an SE for the dynamic oligopoly model with spillovers, and all SE possess the AME property.

Condition (10) admits a simple interpretation. This condition enforces a form of decreasing returns in the spillover effect. If the spillover effect is too large relative to depreciation—i.e., if (10) fails—then the state of a given firm has positive drift whenever other firms have large states; and in this case we expect that, for some \( f \), the spillover effect can lead to optimal oblivious strategies that yield unbounded growth. On the other hand, when (10) holds, then this effect is controlled, and despite the presence of positive spillovers the state distribution has a light tail in equilibrium and the industry becomes fragmented in the limit.

4.3. Learning-by-doing

Another example that commonly arises in oligopoly settings is learning-by-doing, where firms become more efficient by producing goods. In a learning-by-doing model, the state of the firm
represents its experience level; this grows in response to production, and otherwise depreciates over time.

In this type of model, it is clear that we require a dichotomy between “increasing” and “decreasing” returns to experience. Firms have to produce even in the absence of learning, simply to earn profits in each period. Note that if experience levels continue to grow without bound, then it will be impossible to ensure SE are light-tailed. We show this is in fact sufficient: as long as experience begins to depreciate at sufficiently large states (in a sense we make precise), then SE exist, the market becomes fragmented under SE in the limit, and the AME property holds.

We now describe our model; the variant we study is inspired by Fudenberg and Tirole [20].

States. We let the state $x_{i,t}$ represent the cumulative experience level of a firm at time $t$; this represents the knowledge accumulated through past production.

Actions. The action $a_{i,t}$ represents the firm’s output (i.e., goods produced) at time $t$. We consider a model in which firms compete on quantity; thus firms are coupled to each other through their actions. As discussed in Section 3.5, such an extension can be accommodated within our framework by restricting pure actions to lie on a finite subset $S = \{0, 1, \ldots, s_{max}\}$ of the integers.6

Payoffs. At each time period, firms produce goods and compete in a market with $n$ consumers. Let $P_n(\cdot) \geq 0$ be the inverse demand function for a market size of $n$. For state $x$, pure action $s$, and population state-action profile $f$, we can write the payoff function as $\pi(x, s, f, m) = s P_n(s + (m - 1) \sum x', s' f(x', s')) - C(x, s)$, where the argument of $P_n$ is the aggregate output (from $m$ firms) in the market. Note that $f$ is a distribution over state-action pairs. Here, $C(x, s)$ denotes the cost of producing quantity $s$ when the firm’s experience level is $x$. We assume that $C$ is nonnegative, decreasing, and convex in $x$; is increasing and convex in $s$; and has decreasing differences between $x$ and $s$. Consider a limiting case where both the number of firms $m$ and the market size $n$ become large at the same rate. We assume that there exists a limiting decreasing continuous demand function $P$ such that the limit profit function is given by $\pi(x, s, f) = s P(\sum x', s' f(x', s')) - C(x, s)$. Note that the limiting case represents perfect competition as firms become price takers.

Transition dynamics. A firm’s cumulative experience is improved as it produces more goods since it learns from the production process. On the other hand, experience capital depreciates over time due to “organizational forgetting.” We assume that a firm’s experience evolves independent of the experience level or the output of other firms in the market. For concreteness, we assume the transition dynamics are the same as those described in Section 4.1.

Discussion. Let $\lim_{x \to \infty} C(x, s) = C(s)$, that is, $C(s)$ is the cost of producing quantity $s$ for a firm with infinite experience. Our main result for this model is the following proposition. The proof can be found in Section 7.3.

**Proposition 3.** Let $s^*$ be the production level that maximizes $s P(0) - C(s)$. Suppose that for all sufficiently large $x$ and all actions $s \in [0, s^*)$, we have $\sum_{x', x} P(x' | x, s) < x$; i.e., the state has negative drift at all such pairs $(x, s)$. Then there exists an SE for the learning-by-doing model, and all SE possess the AME property.

Observe that $sp - C(x, s)$ is the single period profit to a firm when the market price is $p$, the firm produces quantity $s$, and its experience level is $x$. Generally speaking, because of learning,

---

6 This amounts to discretizing the action space of production quantities. In this case, we allow for mixed strategies to ensure existence of SE (see Proposition 5). However, note that in many models of interest, under the appropriate concavity assumptions, this is not very restrictive as firms will mix between two adjacent pure actions in equilibrium.
firms at low experience levels face strong incentives to increase their experience, leading them to produce beyond the single period optimal quantity. However, for firms at high experience levels, the choice of optimal quantity is driven primarily by maximization of single period profit (because $C(x, s)$ is decreasing and convex in $x$). The quantity $s^*$ is an upper bound on the maximizer of single period profits, so the drift condition in the proposition ensures that at high experience levels, firms’ maximization of single period profit does not continue to yield unbounded growth in the experience level.\footnote{For example, consider $C(x, s) = s/x$. Then $s^*$ is the largest allowable pure action, hence, the condition requires that all actions have negative drift for sufficiently large experience levels. For a less restrictive case, consider $C(x, s) = s^2/x + s^2/c$. Then, $s^* = cP(0)/2$, so the condition requires that all actions less than or equal to $cP(0)/2$ eventually have negative drift.}

The condition requires that the transition kernel must exhibit sufficiently strong decreasing returns to scale; as long as the possible productivity gains induced by learning-by-doing are reduced at larger states, light-tailed SE will exist and the market becomes fragmented in the limit. However, if there are not diminishing returns to learning-by-doing, then a firm’s experience level will grow without bound and hence a light-tailed SE may not exist. This is consistent with prior observations: an industry for which learning-by-doing is prevalent may naturally become concentrated over time [13].

5. Theory: existence

In this section, we study the existence of light-tailed stationary equilibria. We recall that $(\mu, f)$ is an SE if and only if $f$ is a fixed point of $\Phi(f) = D(\mathcal{P}(f), f)$, such that $\mu \in \mathcal{P}(f)$ and $f \in D(\mu, f)$. Thus our approach is to find conditions under which the correspondence $\Phi$ has a fixed point; in particular, we aim to apply Kakutani’s fixed point theorem to $\Phi$ to find an SE.

Kakutani’s fixed point theorem requires three essential pieces: (1) compactness of the range of $\Phi$; (2) convexity of both the domain of $\Phi$, as well as $\Phi(f)$ for each $f$; and (3) appropriate continuity properties of the operator $\Phi$. It is clear, therefore, that our analysis requires topologies on both the set of possible strategies and the set of population states. For the set of oblivious strategies $\mathcal{M}_O$, we use the topology of pointwise convergence.

For the set of population states, we recall that a key concept in our analysis is that of “light-tailed” population states. To formalize this notion, for the set of population states we consider a topology induced by the $1$-$p$ norm.

Definition 9. Given $p > 0$, the $1$-$p$ norm of a function $f: \mathcal{X} \to \mathbb{R}$ is given by:

$$\|f\|_{1-p} = \sum_{x \in \mathcal{X}} \|x\|_p |f(x)|,$$

(11)

where $\|x\|_p$ is the usual $p$ norm of a vector: $\|x\|_p = (\sum_{i=1}^d |x_i|^p)^{1/p}$.

Let $\mathcal{F}_p$ be the set of all possible population states on $\mathcal{X}$ with finite $1$-$p$ norm, i.e., $\mathcal{F}_p = \{f \in \mathcal{F}: \|f\|_{1-p} < \infty\}$. The requirement $f \in \mathcal{F}_p$ imposes a light-tail condition over the population state $f$. The exponent $p$ controls the weight in the tail of the population state: distributions with finite $1$-$p$ norms for larger $p$ have lighter tails. The condition essentially requires that larger states must have a small probability of occurrence under $f$. As we discussed in the context of...
our examples, light-tailed SE imply that the market structure becomes fragmented in the limit of a large number of firms.

We start with the following restatement of Kakutani’s theorem.

**Theorem 1** (Kakutani–Fan–Glicksberg). Suppose there exists a set \( C \subseteq \mathfrak{X}_p \) such that (1) \( C \) is convex and compact (in the 1-p norm), with \( \Phi(C) \subseteq C \); (2) \( \Phi(f) \) is convex and nonempty for every \( f \in \mathcal{E} \); and (3) \( \Phi \) has a closed graph on \( \mathcal{E} \). Then there exists a stationary equilibrium \((\mu, f)\) with \( f \in C \).

In the remainder of this section, we find exogenous conditions on model primitives to ensure these requirements are met. We tackle them in reverse order. We first show that under an appropriate continuity condition, \( \Phi \) has a closed graph. Next, we study conditions under which \( \Phi(f) \) can be guaranteed to be convex. Finally, we provide conditions on model primitives under which there exists a compact, convex set \( C \) with \( \Phi(F) \subseteq C \). The conditions we provide suffice to guarantee that \( \Phi(f) \) is nonempty for all \( f \in \mathcal{E} \). Taken together our conditions ensure existence of SE, as well as an additional stronger characterization: all SE are light-tailed, i.e., they have finite 1-p norm. This fact will allow us to show that every SE satisfies the AME property in the next section.

5.1. Closed graph

In this section we develop conditions to ensure the model is appropriately “continuous.” Before stating the desired assumption, we introduce one more piece of notation. Without loss of generality, we can view the state Markov process in terms of the increments from the current state. In particular, we can write

\[ x_{i,t+1} = x_{i,t} + \xi_{i,t}, \]

where \( \xi_{i,t} \) is a random increment distributed according to the probability mass function \( Q(\cdot | x, a, f) \) defined by

\[ Q(z' | x, a, f) = P(x + z' | x, a, f). \]

Note that \( Q(z' | x, a, f) \) is positive for only those \( z' \) such that \( x + z' \in \mathcal{X} \). We make the following assumptions over model primitives.

**Assumption 1** (Continuity).

1. **Compact action set.** The set of feasible actions for a player, denoted by \( \mathcal{A} \), is compact.
2. **Bounded increments.** There exists \( M \geq 0 \) such that, for all \( z \) with \( \|z\|_\infty > M \), \( Q(z | x, a, f) = 0 \), for all \( x \in \mathcal{X} \), \( a \in \mathcal{A} \), and \( f \in \mathcal{F} \).
3. **Growth rate bound.** There exist constants \( K \) and \( n \in \mathbb{Z}_+ \) such that \( \sup_{a \in \mathcal{A}, f \in \mathcal{F}} |\pi(x, a, f)| \leq K(1 + \|x\|_\infty)^n \) for every \( x \in \mathcal{X} \), where \( \|\cdot\|_\infty \) is the sup norm.
4. **Payoff and kernel continuity.** For each fixed \( x, x' \in \mathcal{X} \) and \( f \in \mathcal{F} \), the payoff \( \pi(x, a, f) \) and the kernel \( P(x' | x, a, f) \) are continuous in \( a \in \mathcal{A} \).

In addition, for each fixed \( x, x' \in \mathcal{X} \), the payoff \( \pi(x, a, f) \) and the kernel \( P(x' | x, a, f) \) are jointly continuous in \( a \in \mathcal{A} \) and \( f \in \mathcal{F}_p \) (where \( \mathcal{F}_p \) is endowed with the 1-p norm).[^9]

[^8]: \( \Phi \) has a closed graph if the set \( \{(f, g): g \in \Phi(f)\} \subseteq \mathcal{F}_p \times \mathcal{F}_p \) is closed (where \( \mathcal{F}_p \) is endowed with the 1-p norm).
[^9]: Here we view \( P(x' | x, a, f) \) as a real valued function of \( a \) and \( f \), for fixed \( x, x' \); note that since we have also assumed bounded increments, this notion of continuity is equivalent to assuming that \( P(\cdot | x, a, f) \) is jointly continuous in \( a \) and \( f \), for fixed \( x \), with respect to the topology of weak convergence on distributions over \( \mathcal{X} \).
The assumptions are fairly mild and are satisfied in a variety of models of interest. For example, all models in Section 4 satisfy it. The first assumption is standard. We also place a finite (but possibly large) bound on how much an agent’s state can change in one period (Assumption 1.2), an assumption that is reasonably weak. The polynomial growth rate bound on the payoff is quite weak, and serves to exclude the possibility of strategies that yield infinite expected discounted payoff.

Finally, Assumption 1.4 ensures that the impact of action on payoff and transitions is continuous. It also imposes that the payoff function and transition kernel are “smooth” functions of the population state under an appropriate norm. This assumption precludes, for example, payoff functions that have a winner-takes-all structure, in which an agent growing to a state larger than all of its competitors garners all available profits, while the rest of agents get zero profits. In particular, this might be the case in certain resource allocation or procurement settings with indivisible goods.

We note that when $\mathcal{X}$ is finite, then $\|f\|_{1-p}$ induces the same topology as the standard Euclidean norm. However, when $\mathcal{X}$ is infinite, the $1-p$-norm weights larger states higher than smaller states. This assumption is appropriate in many applications where competitors at larger states have a greater impact on the payoff of a given player. More specifically, continuity of the payoff in $f$ in the $1-p$ norm implies that changes in the fraction of agents in larger individual states have a larger impact in the payoff compared to changes in smaller states; this impact is controlled by the weights $\|x\|_p^p$ in the definition (11).10 Given a particular model, the exponent $p$ should be chosen to ensure continuity of the payoff and transition kernel.11 The following proposition establishes that the continuity assumptions embodied in Assumption 1 suffice to ensure that $\Phi$ has a closed graph.

**Proposition 4.** Suppose that Assumption 1 holds. Then $\Phi$ has a closed graph on $\mathcal{F}_p$.

### 5.2. Convexity

Next, we develop conditions to ensure that $\Phi(f)$ is convex. We first provide a result for mixed strategies and then a result for pure strategies.

#### 5.2.1. Mixed strategies

We start by considering a simple model, where the action set $\mathcal{A}$ is the simplex of randomized actions on a base set of finite pure actions. This setting is particularly useful when we assume players are coupled through actions (see Section 3.5). Formally, we have the following definition.

**Definition 10.** An anonymous stochastic game has a finite action space if there exists a finite set $S$ such that the following three conditions hold:

1. $\mathcal{A}$ consists of all probability distributions over $S$: $\mathcal{A} = \{a \geq 0: \sum_s a(s) = 1\}$.

---

10 For example, suppose that $\mathcal{X} = \mathbb{Z}$. Then the continuity assumption implies that for all $\epsilon > 0$, there exists a $\delta > 0$, such that for all $f, f' \in \mathcal{F}_p$ with $\sum_{x \in \mathbb{Z}} x^p |f(x) - f'(x)| < \delta$, there holds $|\pi(x, a, f) - \pi(x, a, f')| < \epsilon$. Therefore, the payoff function is more sensitive to changes in the fraction of firms at larger individual states.

11 See Section 4 and Section 7 for concrete examples. For example, in Section 4.1 the payoff function depends on the distribution $f$ via its $\theta_1$ moment so it is natural to endow the set of distributions with the $1-p$ norm with $p = \theta_1$. 
2. \( \pi(x, a, f) = \sum_s a(s) \pi(x, s, f) \), where \( \pi(x, s, f) \) is the payoff evaluated at state \( x \), population state \( f \), and pure action \( s \).

3. \( P(x' | x, a, f) = \sum_s a(s) P(x' | x, s, f) \), where \( P(x' | x, s, f) \) is the kernel evaluated at states \( x' \) and \( x \), population state \( f \), and pure action \( s \).

Essentially, the preceding definition allows inclusion of randomized strategies in our search for SE. This model inherits Nash’s original approach to establishing existence of an equilibrium for static games, where randomization induces convexity on the strategy space. We show next that in any game with finite action spaces, the set \( \Phi(f) \) is always convex.

**Proposition 5.** Suppose Assumption 1 holds. In any anonymous stochastic game with a finite action space, \( \Phi(f) \) is convex for all \( f \in \mathcal{F} \).

The preceding result ensures that if randomization is allowed over a set of finite actions, then the map \( \Phi \) is convex-valued. We conclude by noting that another simplification is possible when working with a finite action space. In particular, it is straightforward to show that if Assumption 1 holds for the payoff and transition kernel over all pure actions, then it also holds for the payoff and transition kernel over all mixed actions; Proposition 4 follows similarly. The proof follows in an easy manner using the linearity of the payoff and transition kernel. This is a valuable insight, since in applications it simplifies the complexity of checking the model assumptions necessary to guarantee existence of an equilibrium. We discuss a similar point in Section 5.3.

### 5.2.2. Pure strategies

In contrast to the preceding section, many relevant applications typically require existence of equilibria in pure strategies. For such examples, we employ an approach based on the following proposition.

**Proposition 6.** Suppose that \( \mathcal{P}(f) \) is a singleton for all \( f \in \mathcal{F} \). Then \( \Phi(f) \) is convex for all \( f \in \mathcal{F} \).

The proof is straightforward: \( \mathcal{D}(\mu, f) \) is convex-valued for any fixed \( \mu \) and \( f \), since the set of invariant distributions for the kernel defined by \( \mu \) and \( f \) are identified by a collection of linear equations. Thus if \( \mathcal{P}(f) \) is a singleton, then \( \Phi(f) = \mathcal{D}(\mathcal{P}(f), f) \) will be convex.

We now provide two different assumptions over model primitives that guarantee that \( \mathcal{P}(f) \) is a singleton, for all \( f \in \mathcal{F} \). The first assumption is a condition introduced by Doraszelski and Satterthwaite [15] and is described in detail there. The assumption has found wide application in dynamic oligopoly models.

**Assumption 2.**

1. The state space is scalar, i.e., \( \mathcal{X} \subseteq \mathbb{Z}_+ \), and the action space \( \mathcal{A} \) is a compact interval of the real numbers.
2. The payoff \( \pi(x, a, f) \) is strictly decreasing and concave in \( a \) for fixed \( x \) and \( f \).
3. For all \( f \in \mathcal{F} \), the transition kernel \( \mathcal{P} \) is unique investment choice (UIC) admissible: there exist functions \( g_1, g_2, g_3 \) such that \( \mathcal{P}(x' | x, a, f) = g_1(x, a, f)g_2(x', x, f) + g_3(x', x, f) \), \( \forall x', x, a, f \), where \( g_1(x, a, f) \) is strictly increasing and strictly concave in \( a \).
The preceding conditions ensure that for all population states $f$ and initial states $x$, and all continuation value functions, the maximization problem in the right hand side of Bellman’s equation (cf. (15) in Appendix C) is strictly concave, or that the unique maximizer is a corner solution.

The previous assumption requires a single-dimensional state space and action space. Our next assumption imposes a different set of conditions over the payoff and the transition kernel, and allows for multi-dimensional state and action spaces. Before providing our second condition, we require some additional terminology. Let $S \subset \mathbb{R}^n$. We say that a function $g : S \rightarrow \mathbb{R}$ is nondecreasing if $g(x') \geq g(x)$ whenever $x' \geq x$ (where we write $x' \geq x$ if $x'$ is at least as large as $x$ in every component). We say $g$ is strictly increasing if the inequality is strict. Let $P_\theta$ be a family of probability distributions on $X$ indexed by $\theta \in S$. Given a nondecreasing function $u : X \rightarrow \mathbb{R}$, define $E_\theta[u] = \sum_x u(x) P_\theta(x)$. We say that $P_\theta$ is stochastically nondecreasing in the parameter $\theta$, if $E_\theta[u]$ is nondecreasing in $\theta$ for every nondecreasing function $u$. Similarly, we say that $P_\theta$ is stochastically concave in the parameter $\theta$ if $E_\theta[u]$ is a concave function of $\theta$ for every nondecreasing function $u$. We say that $P_\theta$ is strictly stochastically concave if, in addition, $E_\theta[u]$ is strictly concave for every strictly increasing function $u$. We have the following assumption.

**Assumption 3.**

1. The action set $A$ is convex.
2. The payoff $\pi(x, a, f)$ is strictly increasing in $x$ for fixed $a$ and $f$, and the kernel $P(\cdot | x, a, f)$ is stochastically nondecreasing in $x$ for fixed $a$ and $f$.
3. The payoff is concave in $a$ for fixed $x$ and $f$, and the kernel is stochastically concave in $a$ for fixed $x$ and $f$, with at least one of the two strictly concave in $a$.

The following result shows the preceding conditions on model primitives ensure the optimal oblivious strategy is unique.

**Proposition 7.** Suppose Assumption 1 holds, and that at least one of Assumption 2 or 3 holds. Then $P(f)$ is a singleton, and thus $\Phi(f)$ is convex for all $f \in \mathcal{F}$.

5.3. Compactness

In this section, we provide conditions under which we can guarantee the existence of a compact, convex, nonempty set $C$ such that $\Phi(C) \subset C$. The assumptions we make are closely related to those needed to ensure that $\Phi(f)$ is nonempty. To see the relationship between these results, observe that in Lemma 2 in Appendix C, we show that under Assumption 1 an optimal oblivious strategy always exists for any $f \in \mathcal{F}$. Thus to ensure that $\Phi(f)$ is nonempty, it suffices to show that there exists at least one such strategy that possesses an invariant distribution. Our approach to demonstrating existence of an invariant distribution is based on the Foster–Lyapunov criterion [37]. Intuitively, this criterion checks whether the process that describes the evolution of an agent eventually has “negative” drift and in this way controls for the growth of the agent’s state. This same argument also allows us to bound the moments of the invariant distribution—precisely what is needed to find the desired set $C$ that is compact in the 1-$p$ norm.

One simple condition under which $\Phi(f)$ is nonempty is that the state space is finite; any Markov chain on a finite state space possesses at least one positive recurrent class. In this case the entire set $\mathcal{F}$ is compact in the 1-$p$ norm. Thus we have the following result.
Proposition 8. Suppose Assumption 1 holds, and that the state space $\mathcal{X}$ is finite. Then $\Phi(f)$ is nonempty for all $f \in \mathcal{F}$, and $\mathcal{F}$ is compact in the $1-p$ norm.

We now turn our attention to the setting where the state space may be unbounded; for notational simplicity, in the remainder of the section we assume $\mathcal{X} = \mathbb{Z}_+^d$. In this case, we must make additional assumptions to control for the agent’s growth; these assumptions ensure the optimal strategy does not allow the state to become transient, and also allows us to bound moments of the invariant distribution of any optimal oblivious strategy.

In the sequel we restrict attention to multiplicatively separable transition kernels, as defined below.

Definition 11. The transition kernel is multiplicatively separable if there exist transition kernels $P_1, \ldots, P_d$ such that for all $x, x' \in \mathcal{X}, a \in A, f \in \mathcal{F}$, there holds $P(x' | x, a, f) = \prod_{\ell=1}^d P_{\ell}(x'_\ell | x_\ell, a_\ell, f)$. In this case we let $Q_1, \ldots, Q_d$ be the coordinatewise increment transition kernels; i.e., $Q_\ell(z_\ell | x, a, f) = P_{\ell}(x_\ell + z_\ell | x_\ell, a_\ell, f)$, for $z$ such that $x + z \in \mathcal{X}$.

This is a natural class of dynamics in models with multi-dimensional state spaces. We note that if $\mathcal{X}$ is one-dimensional, the definition is vacuous. We introduce the following assumption.

Assumption 4.

1. For all $\Delta \in \mathbb{Z}_+^d$, there holds $\limsup_{\|x\|_\infty \to \infty} \sup_{a \in A, f \in \mathcal{F}} \pi(x + \Delta, a, f) - \pi(x, a, f) \leq 0$.
2. The transition kernel $P$ is multiplicatively separable.
3. For $\ell = 1, \ldots, d$, $P_\ell(\cdot | x, a, f)$ is stochastically nondecreasing in $x \in \mathcal{X}$ and $a \in A$ for fixed $f \in \mathcal{F}$.
4. For $\ell = 1, \ldots, d$, and for each $a \in A$ and $f \in \mathcal{F}$, $Q_\ell(\cdot | x, a, f)$ is stochastically nonincreasing in $x \in \mathcal{X}$. Further, for all $x \in \mathcal{X}$, $\sup_f \sum_{z_\ell} Q_\ell(z_\ell | x, a, f)$ is continuous in $a$.
5. There exists a compact set $\mathcal{A}' \subset A$, a constant $K'$, and a continuous, strictly increasing function $\kappa : \mathbb{R}_+ \to \mathbb{R}_+$ with $\kappa(0) = 0$, such that:
   (a) For all $x \in \mathcal{X}, f \in \mathcal{F}, a \not\in \mathcal{A}'$, there exists $a' \in \mathcal{A}'$ with $a' \leq a$, such that $\pi(x, a', f) - \pi(x, a, f) \geq \kappa(\|a' - a\|_\infty)$.
   (b) For all $\ell$, and all $x'$ such that $x'_\ell \geq K'$, $\sup_{a' \in \mathcal{A}'} \sup_{f \in \mathcal{F}} \sum_{z_\ell} z_\ell Q_\ell(z_\ell | x', a', f) < 0$.

Some of the previous conditions are natural, while others impose a type of “decreasing returns to higher states.” First, we discuss the former. Multiplicative separability (Assumption 4.2) is natural. The first part of Assumption 4.3 is also fairly weak. The transition kernel is stochastically nondecreasing in state in models for which the state is persistent, in the sense that a larger state today increases the chances of being at a larger state tomorrow. The transition kernel is stochastically nondecreasing in action in models where larger actions take agents to larger states.

Assumption 4.1, 4.4, and 4.5 impose a form of “decreasing returns to higher states” in the model. In particular, Assumption 4.1 ensures the marginal gain in payoff by increasing one’s state becomes nonpositive as the state grows large. This assumption is used to show that for large enough states agents effectively become myopic; increasing the state further does not provide additional gains. Assumption 4.5 then implies that as the state grows large, optimal actions produce negative drift inducing a “light-tail” on any invariant distribution of the resulting optimal oblivious strategy. The set $\mathcal{A}'$ can be understood as (essentially) the set of actions that maximize the single period payoff function. Assumption 4.5 is often natural because in many models of
interest increasing the state beyond a certain point is costly and requires dynamic incentives; agents will take larger actions that induce positive drift only if they consider the future benefits of doing so.

The first part of Assumption 4.4 imposes a form of decreasing returns in the transition kernel. The second part of Assumption 4.4 will hold if, for example, the transition kernel is coordinate-wise stochastically nonincreasing in \( f \in \mathcal{F} \) (with respect to the first order stochastic dominance ordering) and Assumption 1 holds. In this case \( \sup_f \sum_{z} z Q(z | x, a, f) = \sum_{z} z Q(z | x, a, f) \), where \( f \) is the distribution that places all its mass at state 0.

Much of the difficulty in the proof of the result lies in ensuring that the tail of any invariant distribution obtained from an optimal oblivious strategy is uniformly light over the image of \( \Phi \). The fact that Assumptions 4.1, 4.4, and 4.5 are uniform over \( f \) are crucial for this purpose.

Under the preceding assumptions we have the following result.

**Proposition 9.** Suppose \( X = \mathbb{Z}_d^+ \), and Assumptions 1 and 4 hold. Then \( \Phi(f) \) is nonempty for all \( f \in \mathcal{F} \), and there exists a compact, convex, nonempty set \( \mathcal{C} \) such that \( \Phi(\mathcal{F}) \subset \mathcal{C} \).

Note that the preceding result ensures \( \Phi(f) \subset \mathcal{C} \) for all \( f \in \mathcal{F} \).

We conclude this section with a brief comment regarding finite action spaces, cf. Definition 10. The key observation we make is that if Assumption 4 holds with respect to the pure actions—i.e., with \( A \) replaced by \( S \)—then the same result as Proposition 9 holds for mixed actions. A nearly identical argument applies to establish the result.

### 5.4. Summary of results

The previous results can be summarized by the following corollary that imposes conditions over model primitives to guarantee the existence of a light-tailed SE.

**Corollary 1.** Suppose that (1) Assumption 1 holds; (2) either the game has a finite action space, or Assumption 2 holds, or Assumption 3 holds; and (3) either the state space \( X \) is finite, or \( X = \mathbb{Z}_d^+ \) and Assumption 4 holds. Then, there exists an SE, and every SE \((\mu, f)\) has \( f \in \mathcal{F}_p \).

As we have discussed and as one can show in the examples in Section 4, many models of interest satisfy Assumption 1 and Assumption 2 or 3 (or, more generally, some condition that guarantees uniqueness of the optimal oblivious strategy); see Section 7. Hence, if these models have a finite state space, existence of SE follows immediately. If the state space is unbounded, the only condition that remains to be checked to guarantee existence of SE is Assumption 4. As discussed in the examples in Section 4, this condition imposes a form of “decreasing returns to higher states.”

We conclude by emphasizing that under the assumptions of the existence result all SE have \( f \in \mathcal{F}_p \); in other words, all the resulting SE have a light-tail. In the context of our examples, as previously discussed, this implies that all SE yield a fragmented market structure. In addition, the light-tail property, together with Assumption 1, will be used in the next section to ensure that the AME property holds.
6. Theory: approximation

In this section we show that under the assumptions of the preceding section, any SE \((\mu, f)\) possesses the AME property. We emphasize that the AME property is essentially a continuity property in the population state \(f\). Under reasonable assumptions, we show that the time \(t\) population state in the system with \(m\) players, \(f^{(m)}_{-i,t}\), approaches the deterministic population state \(f\) in an appropriate sense almost surely for all \(t\) as \(m \to \infty\); in particular, this type of uniform law of large numbers will hold as long as \(f\) has tails that are sufficiently light. If \(f^{(m)}_{-i,t}\) approaches \(f\) almost surely, then informally, if the payoff satisfies an appropriate continuity property in \(f\), we should expect the AME property to hold. The remainder of the section is devoted to formalizing this argument.

Theorem 2 (AME). Suppose Assumption 1 holds. Let \((\mu, f)\) be a stationary equilibrium with \(f \in \mathcal{F}_p\). Then the AME property holds for \((\mu, f)\).

Observe that Assumption 1 is also required for the existence of SE that satisfy \(f \in \mathcal{F}_p\). In this sense, under our assumptions, the AME property is a direct consequence of existence. This relationship between existence and the AME property is a significant insight of our work.

The proof of the AME property exploits the fact that the 1-\(p\) norm of \(f\) must be finite (since \(f \in \mathcal{F}_p\)) to show that \(\|f^{(m)}_{-i,t} - f\|_{1-p} \to 0\) almost surely as \(m \to \infty\); i.e., the population state of other players approaches \(f\) almost surely under an appropriate norm. Continuity of the payoff \(\pi\) in \(f\), together with the growth rate bounds in Assumption 1, yields the desired result.

In practice, the light-tail condition—i.e., the requirement that \(f \in \mathcal{F}_p\)—ensures that an agent’s state rarely becomes too large under the invariant distribution \(f\) associated with the dynamics (6). Weintraub et al. [46] provide a similar result in a dynamic industry model with entry and exit. Our result is more general in terms of the definition of the AME property, as well as the payoff functions and transition kernels considered. In particular, we allow for dependence of the transition kernel on the population state. This necessitates a significantly different proof technique, since agents’ states do not evolve independently in general. We note that the light-tail condition is consequential, as it is possible to construct examples for which SE exist, but \(f \notin \mathcal{F}_p\) and the AME property does not hold [46].

We conclude by noting that in many models of interest it is more reasonable to assume that the payoff function explicitly depends on the number of agents. To study these environments, we consider a sequence of payoff functions indexed by the number of agents, \(\pi_m(x, a, f)\). Here, the profit function \(\pi\) is a limit: \(\lim_{m \to \infty} \pi_m(x, a, f) = \pi(x, a, f)\). (See Section 4 for concrete examples.) In this case, if the number of players is \(m\), the actual expected net present value is defined with \(\pi_m\), hence, the payoff function in the AME property depends on \(m\). In Appendix B we show that under a strengthening of Assumption 1, Theorem 2 can be generalized to this setting.

7. Examples revisited

In this section we revisit each of the examples presented in Section 4 and show that all the propositions for these examples are consequences of Corollary 1 and Theorem 2. This establishes the key connection in the paper between existence of SE and the AME property on one hand, and the impact of model primitives on market structure on the other hand. In particular, our
conditions over model primitives imply that all SE are light-tailed, and therefore, in all SE the industry yields a fragmented market structure, and the AME property is satisfied.

Formally, recall that the conditions required to establish the main results of this paper are Assumption 1 (used to ensure continuity properties); Assumption 2 and/or 3 (used to ensure convexity of the image of \( \Phi \)); and Assumption 4 (used to ensure the existence of a compact subset \( \mathcal{C} \subset \mathcal{F} \) such that \( \Phi(\mathcal{C}) \subset \mathcal{C} \)). Of these properties, continuity and convexity are typically straightforward to guarantee in each of the models we consider below. Thus we primarily focus on the role of Assumption 4.

7.1. Dynamic oligopoly models

In this section, we provide the proof of Proposition 1. Note that the payoff function depends on the distribution \( f \) via its \( \theta_1 \) moment, and hence we endow the set of distributions with the topology induced by the \( 1-p \) norm with \( p = \theta_1 \). Since the payoff is continuous and nonincreasing in the \( \theta_1 \) moment of \( f \) and the transition kernel is independent of \( f \), it is straightforward to check that Assumption 1 holds. In addition, Doraszelski and Satterthwaite [15] show that the transition kernel of this model satisfies Assumption 2 (it can also be shown that Assumption 3 is satisfied). Thus the desired result is reduced to determining whether Assumption 4 holds. It is straightforward to check that Assumptions 4.1–4 hold; we omit the details. Assumption 4.5 holds because positive drift is costly, as the kernel defined above exhibits depreciation; in particular, it suffices to set \( \mathcal{A}' = \{0\} \). Thus the central condition to check in this model is Assumption 4.1. This assumption holds if and only if \( \theta_1 < 1 \); in this case, \( \sup_{a,f} \pi(x + \Delta, a, f) - \pi(x, a, f) \to 0 \) as \( x \to \infty \) for all \( \Delta > 0 \). Using Corollary 1 and Theorem 2, the result follows.

Thus, existence of SE and the AME property are closely tied to the parameter \( \theta_1 \) which represents how much consumers value the quality of the product. For \( \theta_1 < 1 \), the firms have decreasing marginal returns in their payoff from increasing their state. This ensures that the Markov process associated with a single firm optimization process is stable which in turn ensures that the range of \( \Phi \) is compact. As discussed earlier, this condition leads to a natural separation between industries where we expect to see a fragmented market structure and the industries where market concentration is likely to result in the limit.

7.2. Dynamic oligopoly models with positive spillovers

In this section we provide the proof of Proposition 2. Assumptions 1 and 2 follow as in the preceding result; the proof is omitted. Again we focus on Assumption 4. Assumptions 4.1, 4.2, 4.3, and the first part of 4.4 hold as before; we omit the details. The key assumptions that we need to verify are thus the second part of Assumption 4.4, and Assumption 4.5.

Observe that the maximum possible value of the effective investment when a firm takes action \( a \) is \( e_{\text{max}}(a) \triangleq a + \gamma \sup_{y} \xi(y) \). A straightforward calculation yields:

\[
\sup_{a} \sum_{z} z Q(z \mid x, a, f) = (1 - \delta) \left( \frac{\alpha e_{\text{max}}(a)}{1 + \alpha e_{\text{max}}(a)} \right) - \delta \left( \frac{1}{1 + \alpha e_{\text{max}}(a)} \right)
\]

\[
= \frac{\alpha e_{\text{max}}(a)}{1 + \alpha e_{\text{max}}(a)} - \delta.
\]

(12)

It follows from the definition of the transition kernel that the second part of Assumption 4.4 holds. In order for Assumption 4.5 to hold with \( \mathcal{A}' = \{0\} \), it follows that we need:
\[ \gamma < \frac{\delta}{(1 - \delta)\alpha \sup_y \zeta(y)} \]

Using Corollary 1 and Theorem 2, we conclude that the result of the proposition follows if (10) holds.

For industries with spillovers, the compactness assumptions require that the spillover effect is not too large relative to depreciation. This along with decreasing marginal returns in the payoff ensures that the firms do not have unbounded growth in their state. As a result, the SE market structure becomes fragmented in the limit of a large number of firms.

7.3. Learning-by-doing

In this section, we provide the proof of Proposition 3. Since \( P \) is decreasing and \( C(x, s) \) is decreasing in \( x \), Assumption 1 follows in a straightforward manner in this model, as long as \( P \) is continuous. Since this is a model with finite action spaces, the result of Proposition 5 also applies. Thus, as before, the proof is reduced to determining whether Assumption 4 holds for the given model. As in the preceding examples, it is straightforward to check that Assumptions 4.2, 4.3, and 4.4 hold. Note that \( \pi(x + \Delta, s, f) - \pi(x, s, f) = C(x, s) - C(x + \Delta, s) \) for all \( x, s, f \) and \( \Delta \geq 0 \), and the action space is finite. Thus Assumption 4.1 follows since \( C(x, s) \) is nonnegative, decreasing, and convex in \( x \).

Therefore, our focus turns to Assumption 4.5. Using standard supermodularity arguments, it is simple to check that any \( s \) that maximizes \( \pi(x, s, f) \) for some \( x, f \) is contained in the interval \([0, s^*]\). In particular, then, suppose that for all sufficiently large \( x \) and all actions \( s \in [0, s^*] \), we have \( \sum \pi(z | x, s) < 0 \). Then Assumption 4.5 holds, so using Corollary 1 and Theorem 2 the result follows.

In learning-by-doing models, compactness of the image of \( \Phi \) is ensured by requiring that the transition kernel exhibits decreasing returns to higher states. In other words, if the productivity gains induced by learning-by-doing are reduced at larger states, light-tailed SE will exist and the AME property will hold. As discussed earlier this is consistent with the observation that a very strong learning-by-doing effect (that persists even at large scale) will likely lead to market concentration.

8. Conclusions

This paper considered stationary equilibrium in dynamic games with many players. Our main results provide a parsimonious set of assumptions on the model primitives which ensure that an SE exists in a large variety of games. We also showed that the same set of assumptions ensure that SE yield fragmented market structures, and is a good approximation to MPE in large finite games. Through a set of examples, we illustrate that our conditions on model primitives can be naturally interpreted as enforcing “decreasing returns to higher states.”

We conclude by noting a couple of extensions that can be developed for the models described here.

1. Connections between SE and oblivious equilibrium in finite models. In some contexts, particularly in empirical settings, it may be more appropriate to work over a model with a finite number of agents. In these cases, as discussed in Appendix B, it is possible to define an “oblivious equilibrium” for finite models [45]. We conjecture that under some additional
technical conditions over the model primitives we can prove that a sequence of OE satisfies
the AME property.
2. Nonstationary equilibrium. Our focus was on SE because it is of practical interest and has
received significant attention in the literature. We conjecture, however, that our results can
be extended to nonstationary versions of an equilibrium concept based on averaging effects
that could be used to approximate transitional short-run dynamics as oppose to long-run
behavior.

We leave these directions for future research.

Acknowledgments

Appendix A. Extensions to the basic model

A.1. Heterogeneous players

In this appendix, we study anonymous stochastic games with ex-ante heterogeneous players.
To represent this heterogeneity, at the beginning of the game, a player is assigned a type (denoted
by $\theta$) that stays fixed for the entire duration of the game. For simplicity, we assume that the
players’ types are randomly and independently drawn out of a finite set $\Theta$ with a common prior
distribution $\Gamma$. Let $P(\cdot | x, a, f; \theta)$ and $\pi(x, a, f; \theta)$ denote the transition kernel and payoff of a
type $\theta$ player.

To analyze a stochastic game with heterogeneous players, we define a new state as follows.
Let $\hat{x} = (x, \theta)$ be an extended state; if a player’s extended state is $\hat{x}$, we interpret it to mean that
the player is in state $x$ and has a type $\theta$. We let $\hat{X} = \mathcal{X} \times \Theta$ denote the expanded state space.
Let $\hat{f}$ denote a population state over the expanded state space, i.e., $\hat{f}$ is a distribution over $\hat{X}$.
Given $\hat{f}$, we define $F(\hat{f}) \in \mathcal{F}$ by:

$$F(\hat{f})(x) = \sum_{\theta} \hat{f}(x, \theta).$$

We have the following two definitions:

$$\hat{\pi}(\hat{x}, a, \hat{f}) = \pi(x, a, F(\hat{f}); \theta);$$

$$\hat{P}(\hat{x}' | \hat{x}, a, \hat{f}) = \begin{cases} 0, & \text{if } \theta' \neq \theta; \\ P(x' | x, a, F(\hat{f}); \theta), & \text{if } \theta' = \theta. \end{cases}$$

These definitions simply map the payoff and transition kernel with respect to the extended state
back to the payoff and transition kernel in the original game. Now observe that in the new game
defined in this way, it can be verified that if the original game satisfied Assumptions 1, 2 or
3, and 4 for each $\theta$, then the extended game satisfies the same assumptions as well. Thus all
our preceding results apply even in games with heterogeneous players. Because strategies are a function of the extended state, in this case players of different types will use different strategies.

A.2. Coupling through actions

In the main development of this paper, we considered anonymous stochastic games where players are coupled to each other via the population state as defined in Eq. (2); note, in particular, that the population state gives the fraction of players at each state. As discussed in the Introduction, however, in many models of interest the transition kernel and payoff of a player may depend on both the current state and current actions of other players. In particular, the example in Section 4.3 is a model where players are coupled through their actions.

To formally model such a scenario, we consider an m-player stochastic game being played in discrete time over the infinite horizon, where again the payoff and transition kernel of a player are denoted by \( \pi(x, a, f) \) and \( P(\cdot | x, a, f) \) respectively. However, we now assume that \( f \) is a distribution over both states and actions. We refer to \( f \) as the population state-action profile (to distinguish it from just the population state, which is the marginal distribution of \( f \) over \( X \)). For simplicity, since the prior development in this paper assumes state spaces are discrete, for the purposes of this subsection we restrict attention to a game with a finite action space \( S \subseteq \mathbb{Z}^k \), cf. Definition 10; in particular, we assume that players maximize payoffs with respect to randomized strategies over \( S \). Thus the population state-action profile is a distribution over \( X \times S \).

We again let \( x_{i,t} \in X \) be the state of player \( i \) at time \( t \), where \( X \subseteq \mathbb{Z}^d \). We let \( s_{i,t} \in S \) be the (pure) action taken by player \( i \) at time \( t \). Let \( f_{-i,t}^{(m)} \) denote the empirical population state-action profile at time \( t \) in an \( m \)-player game; in other words, \( f_{i,t}^{(m)}(x, s) \) is the fraction of players other than \( i \) at state \( x \) who play \( s \) at time \( t \). With these definitions, \( x_{i,t} \) evolves according to the transition kernel \( P \) as before, i.e., \( x_{i,t+1} \sim P(\cdot | x_{i,t}, a_{i,t}, f_{-i,t}^{(m)}) \).

A player acts to maximize their expected discounted payoff, as before. Note that a potential challenge here is that a player’s time \( t \) payoff and transition kernel depend on the actions of his competitors, which are chosen simultaneously with his own action. Thus to evaluate the time \( t \) expected payoffs and transition kernel, a player must take an expectation with respect to the randomized strategies employed by his competitors.

Our first step is to extend the appropriate assumptions to this game model. Let \( \mathfrak{F} \) now denote the set of all distributions over \( X \times S \), and let \( \mathfrak{F}_p \) denote the set of all distributions in \( \mathfrak{F} \) with finite 1-\( p \) norm as before. Assumptions 1 and 4 thus extend naturally to games with coupling through actions, with these new interpretations of \( \mathfrak{F} \) and \( \mathfrak{F}_p \).

The AME property continues to hold for games with coupling through actions. Recall that in the proof of Theorem 2, we establish that if \((\mu, f)\) is an SE, then \( \| f_{-i,t}^{(m)} - f \|_{1-p} \to 0 \) almost surely for all \( t \), if players’ initial states are sampled independently from \( f \), all players other than \( i \) follow strategy \( \mu \), and player \( i \) follows any strategy. (See Lemma 9 in Appendix E.) In a game with coupling through actions, \( f_{-i,t}^{(m)} \) also tracks the empirical distribution of players’ actions. However, since all players other than \( i \) use the same oblivious strategy \( \mu \), and since the base action space \( S \) is finite, it is straightforward to extend the argument of Lemma 9 to the current setting. The remainder of the existing proof of Theorem 2 carries over essentially unchanged under Assumption 1; for brevity we omit the details.

12 For the purposes of this subsection we assume players are homogeneous.
Next, recall that to prove existence of an SE, we consider two maps: \( P(f) \) (which identifies the set of optimal oblivious strategies given \( f \)), and \( D(\mu, f) \) (which identifies the set of invariant distributions of the Markov process induced by \( \mu \) and \( f \)). The analysis of \( P(f) \) proceeds exactly as before (but with randomized strategies, as discussed in Section 5.2.1). However, in a game with coupling through actions, we redefine \( D(\mu, f) \) to be the set of invariant distributions over \( X \times S \) induced by \( \mu \) and \( f \). In other words, \( f' \in D(\mu, f) \) if and only if there exists a distribution \( g \) over \( X \) such that the following two conditions hold:

\[
g(x') = \sum_x g(x) P(x' \mid x, \mu(x), f), \quad \text{for all } x';
\]

\[
f'(x, s) = g(x) \cdot \mu(x)(s), \quad \text{for all } x, s.
\]

Note that here \( \mu(x)(s) \) is the probability assigned to pure action \( s \) by the randomized strategy \( \mu \) at state \( x \). The first equation requires that \( g \) is an invariant distribution of the state Markov process induced by \( \mu \) and \( f \) (recall Definition 10 of the transition kernel with mixed actions). The second equation requires \( f' \) to be derived from \( g \) in the natural way, via \( \mu \). As before, we let \( \Phi(f) = D(P(f), f) \).

It is now straightforward to show that if Assumption 1 holds, then the result of Proposition 4 holds, i.e., \( \Phi \) has a closed graph. Further, if Assumptions 1 and 4 hold, then the result of Proposition 9 holds as well. From this and the result in Proposition 5 we conclude that under those assumptions, an SE exists, and all SE are light-tailed (i.e., have finite 1-\( p \) norm). The arguments involved are analogous to the existing proofs, and we omit the details.

We conclude by commenting on the restriction that the action space must be finite. From a computational standpoint this is not very restrictive, since in many applications discretization is required or can be used efficiently. From a theoretical standpoint, we can analyze games with general compact Euclidean action spaces using techniques similar to this paper, at the expense of additional measure-theoretic complexity, since now the population state-action profile is a measure over a continuous extended state space.

**Appendix B. Approximation: sequence of payoff functions**

In many models of interest it is more reasonable to assume that the payoff function explicitly depends on the number of agents. To study these environments, in this appendix we consider a sequence of payoff functions indexed by the number of agents, \( \pi_m(x, a, f) \). Here, the profit function \( \pi \) is a limit: \( \lim_{m \to \infty} \pi_m(x, a, f) = \pi(x, a, f) \). See Section 4 for concrete examples.

In this case, the actual expected net present value of a player using a cognizant strategy \( \mu' \) when every other of the \( m - 1 \) players uses an oblivious strategy \( \mu \) is given by Eq. (5), but where \( \pi \) is replaced by \( \pi_m \). That is, if the number of players is \( m \), the payoff obtained each period is given by \( \pi_m \). Hence, with some abuse of notation, for this appendix, we define:

\[
V^{(m)}(x, f \mid \mu', \mu^{(m-1)}) = \mathbb{E} \left[ \sum_{t=0}^{\infty} \beta^t \pi_m(x_i, a_i, f^{(m)}_{-i, t}) \mid x_{i,0} = x, f^{(m)}_{-i,0} = f; \mu_i = \mu', \mu_{-i} = \mu^{(m-1)} \right].
\]  

We generalize Theorem 2 for this setting. First, we need to strengthen Assumption 1.

**Assumption 5.** For each \( m \in \mathbb{Z}_+ \), Assumption 1 holds, with the following strengthened properties.
1. Equicontinuity. The set of functions \( \{ \pi_m(x, a, f) : m \in \mathbb{Z}_+ \} \) is jointly equicontinuous in 
\( a \in A \) and \( f \in \mathfrak{S}_p \).

2. Uniform growth rate bound. There exist constants \( K \) and \( n \in \mathbb{Z}_+ \) such that
\[
\sup_{m \in \mathbb{Z}_+, a \in A, f \in \mathfrak{S}_p} |\pi_m(x, a, f)| \leq K (1 + \|x\|_\infty)^n
\]
for every \( x \in X \).

The following result is more general than Theorem 2, because the payoff function in the AME property depends on \( m \).

**Theorem 3 (AME).** Suppose Assumption 5 holds. Let \((\mu, f)\) be a stationary equilibrium with \( f \in \mathfrak{S}_p \). Then the AME property holds for \((\mu, f)\).

The proof is similar to Theorem 2, but requires an additional step to accommodate the sequence of payoff functions. However, note that similar to Theorem 2, the SE \((\mu, f)\) is fixed and is computed with the limit payoff function \( \pi \). Alternatively, it is possible to define an “oblivious equilibrium” (OE) for each finite model. An OE is similar to SE in the sense that agents optimize assuming that the long run population state is constant; the main difference is that it is defined in a finite model rather than in the limit model. Under a uniform light-tail condition, it can be shown that the sequence of OE satisfies the AME property [45]. In addition, we conjecture that a version of the assumptions that guarantee existence of SE in Section 5, but that applies uniformly over all finite models, would guarantee that such a uniform light-tail condition holds. For clarity of presentation, we chose to work with the SE of the limit model directly.

Moreover, we believe that the existence result for the limit model that we provide is important, because even though OE might exist under mild conditions for each finite model, SE in the limit model may fail to exist. In particular, as we discuss in Section 4, this might be the case in applications that exhibit “increasing returns to scale.” See in particular Sections 4.1, 4.2, and 4.3, for examples of how limit models are derived in specific applications, and also conditions in such models that ensure stationary equilibria provide accurate approximations.

**Appendix C. Existence and AME: preliminary lemmas**

We begin with the following lemma, which follows from the growth rate bound and bounded increments in Assumption 1.

**Lemma 1.** Suppose Assumption 1 holds. Let \( x_0 = x \). Let \( a_t \in A \) be any sequence of (possibly history dependent) actions, and let \( f_t \in \mathfrak{S} \) be any sequence of (possibly history dependent) population states. Let \( x_t \) be the state sequence generated, i.e., \( x_t \sim P(\cdot | x_{t-1}, a_{t-1}, f_{t-1}) \). Then for all \( T \geq 0 \), there exists \( C(x, T) < \infty \) such that \( \mathbb{E}[\sum_{t=T}^{\infty} \beta^t |\pi(x_t, a_t, f_t)| | x_0 = x] \leq C(x, T) \).

Further, \( C(x, T) \to 0 \) as \( T \to \infty \).

**Proof.** Observe that by Assumption 1, the increments are bounded. Thus starting from state \( x \), we have \( \|x_t\|_\infty \leq \|x\|_\infty + tM \). Again by Assumption 1, \( |\pi(x_t, a_t, f_t)| \leq K (1 + \|x_t\|_\infty)^n \). Therefore:

---

13 Let \( \mathcal{X} \) and \( \mathcal{Y} \) be two metric spaces, with metrics \( d_\mathcal{X} \) and \( d_\mathcal{Y} \) respectively. A set of functions \( F \) mapping \( \mathcal{X} \) to \( \mathcal{Y} \) is said to be equicontinuous at \( x_0 \in \mathcal{X} \), if for every \( \epsilon > 0 \), there exists a \( \delta > 0 \) such that \( d_\mathcal{Y}(f(x), f(x_0)) < \epsilon \) for all \( f \in F \) and all \( x \) such that \( d_\mathcal{X}(x_0, x) < \delta \).
Let $C(x, T)$ be the right hand side in the preceding expression. It is easy to check that $C(x, T)$ goes to zero as $T \to \infty$, since the asymptotic behavior is dominated by the leading coefficient $\beta^T$. \qed

We now show that the Bellman equation holds for the dynamic program solved by a single agent given a population state $f$. Given our unbounded state space, our proof involves the use of a weighted sup norm, defined as follows. For each $x \in \mathcal{X}$, let $W(x) = (1 + \|x\|_\infty)^n$. For a function $F : \mathcal{X} \to \mathbb{R}$, define:

$$
\|F\|_{w-\infty} = \sup_{x \in \mathcal{X}} \frac{|F(x)|}{W(x)}.
$$

This is the weighted sup norm with weight function $W$. We let $B(\mathcal{X})$ denote the set of all functions $F : \mathcal{X} \to \mathbb{R}$ such that $\|F\|_{w-\infty} < \infty$.

Let $T_f$ denote the dynamic programming operator with population state $f$: given a function $F : \mathcal{X} \to \mathbb{R}$, we have $(T_f F)(x) = \sup_{a \in \mathcal{A}} \pi(x, a, f) + \beta \sum_{x' \in \mathcal{X}} F(x') P(x' \mid x, a, f)$. We define $T_f^k$ to be the composition of the mapping $T_f$ with itself $k$ times. The following lemma applies standard dynamic programming arguments.

**Lemma 2.** Suppose Assumption 1 holds. For all $f \in \mathcal{F}$, if $F \in B(\mathcal{X})$ then $T_f F \in B(\mathcal{X})$. Further, there exist $k, \rho$ independent of $f$ with $0 < \rho < 1$ such that $T_f$ is a $k$-stage $\rho$-contraction on $B(\mathcal{X})$; i.e., if $F, F' \in B(\mathcal{X})$, then for all $f$: $\|T_f^k F - T_f^k F'\|_{w-\infty} \leq \rho \|F - F'\|_{w-\infty}$.

In particular, value iteration converges to $\tilde{V}^\ast(\cdot \mid f) \in B(\mathcal{X})$ from any initial value function in $B(\mathcal{X})$, and for all $f \in \mathcal{F}$ and $x \in \mathcal{X}$, the Bellman equation holds:

$$
\tilde{V}^\ast(x \mid f) = \sup_{a \in \mathcal{A}} \left\{ \pi(x, a, f) + \beta \sum_{x' \in \mathcal{X}} \tilde{V}^\ast(x' \mid f) P(x' \mid x, a, f) \right\}.
$$

Further, $\tilde{V}^\ast(x \mid f)$ is continuous in $f \in \mathcal{F}_p$.

Finally, there exists at least one optimal oblivious strategy among all (possibly history-dependent, possibly randomized) strategies; i.e., $\mathcal{P}(f)$ is nonempty for all $f \in \mathcal{F}$. An oblivious strategy $\mu \in \mathcal{M}_O$ is optimal given $f$ if and only if $\mu(x)$ achieves the maximum on the right hand side of (15) for every $x \in \mathcal{X}$.

**Proof.** We have the following three properties:

1. By growth rate bound in Assumption 1 we have $\sup_{a} |\pi(x, a, f)|/W(x) \leq K$ for all $x$.
2. We have:

$$
\overline{W}(x) = \sup_{a \in \mathcal{A}} \sum_{x'} P(x' \mid x, a, f) W(x') \leq (1 + \|x\|_\infty + M)^n,
$$

since the increments are bounded (Assumption 1). Thus $\overline{W}(x)/W(x) \leq (1 + M)^n$ for all $x$.
3. Finally, fix $\rho$ such that $0 < \rho < 1$ and let:

$$
\overline{W}_k(x) = \sup_{\mu \in \mathcal{M}_O} E\left[ W(x_k) \mid x_0 = x, \mu \right].
$$
where the state evolves according to $x_{t+1} \sim P(\cdot \mid x_t, \mu(x_t), f)$. By bounded increments in Assumption 1, we have:

$$\beta^k \overline{W}_k(x) \leq \beta^k (1 + \|x\|_\infty + kM)^n \leq \beta^k (1 + kM)^n W(x).$$

By choosing $k$ sufficiently large so that $\beta^k (1 + kM)^n < \rho$, we have:

$$\beta^k \overline{W}_k(x) \leq \rho W(x).$$

Given (1)–(3), by standard arguments (see, e.g., [8]), it follows that $T_f$ is a $k$-stage $\rho$-contraction with respect to the weighted sup norm, value iteration converges to $\tilde{V}^* (\cdot \mid f)$, the Bellman equation holds, and any (stationary, nonrandomized) oblivious strategy that maximizes the right hand side in (15) for each $x \in \mathcal{X}$ is optimal. Observe that since $\tilde{V}^*(\cdot \mid f) \in B(\mathcal{X})$ for any $f$, it follows that $\tilde{V}^*(x \mid f) < \infty$ for all $x$. In fact, by Lemma 1, $|\tilde{V}^*(x \mid f)| \leq C(x, 0)$ for all $x$.

Next we show that $\tilde{V}^*(x \mid f)$ is continuous in $f$. Define $Z(x) = 0$ for all $x$, and let $V_f^{(\ell)} = T_f^\ell Z$. We first show that $V_f^{(\ell)}(x)$ is continuous in $f$. To see this, we proceed by induction. The result is trivially true at $\ell = 0$. Next, observe that $\pi(x, a, f)$ is jointly continuous in $a$ and $f$ for each fixed $x$ by Assumption 1. Suppose $V_f^{(\ell)}(x)$ is continuous in $f$ for each $x$; then $V_f^{(\ell)}(x) P(x' \mid x, a, f)$ is jointly continuous in $a$ and $f$ for each fixed $x, x'$. Since the kernel has bounded increments from Assumption 1, we conclude that $\sum_{x'} V_f^{(\ell)}(x') P(x' \mid x, a, f)$ is jointly continuous in $a$ and $f$ for each fixed $x$. It follows by Berge’s maximum theorem [6] that $V_f^{(\ell+1)}(x)$ is continuous in $f$.

Fix $\epsilon > 0$. Since $T_f$ is a $k$-stage $\rho$-contraction in the weighted sup norm for every $f$, it follows that for all sufficiently large $\ell$, for every $f$ there holds:

$$|V_f^{(\ell)}(x) - \tilde{V}^*(x \mid f)| \leq W(x) \epsilon.$$

So now suppose that $f_n \to f$ in the 1-$p$ norm. Since $V_f^{(\ell)}(x)$ is continuous in $f$, for all sufficiently large $n$ there holds:

$$|V_f^{(\ell)}(x) - V_f^{(\ell)}(x)| \leq \epsilon.$$

Thus using the triangle inequality, for all sufficiently large $n$ we have:

$$|\tilde{V}^*(x \mid f) - \tilde{V}^*(x \mid f_n)| \leq (2W(x) + 1) \epsilon.$$

Since $\epsilon$ was arbitrary it follows that the left hand side approaches zero as $n \to \infty$, as required. Finally, observe that by a similar argument as above,

$$\sum_{x'} \tilde{V}^*(x' \mid f) P(x' \mid x, a, f)$$

is a continuous function of $a$ for each fixed $x$ and $f$; since $\pi(x, a, f)$ is also continuous in $a$ for each fixed $f$, the right hand side of (15) is continuous in $a$ for each fixed $f$. Since $A$ is compact, it follows that there exists an optimal action at each state $x$, and thus there exists an optimal strategy given $f$. \qed
Appendix D. Existence: proof

The proof of Proposition 4 involves applying the continuity properties in Assumption 1 and Lemma 2 to establish $\Phi$ has a closed graph. First, we show that for each $f$, $P(f)$ is compact; and further, that the correspondence $\mathcal{P}$ is upper hemicontinuous on $\mathcal{S}_p$. The main step here is an application of Berge’s maximum theorem to the right hand side of (15). Since the set $\mathcal{D}(\mu, f)$ is defined through a set of linear equations (identifying the steady state distributions of the state dynamics under strategy $\mu$ with population state $f$), a direct continuity argument on the composition of $P$ and $D$ completes the proof. See the longer version of our paper for details [3].

The proof of Proposition 5 uses straightforward convexity arguments; we omit the details of these arguments and instead refer the reader to the longer version of our paper [3].

The proof of Proposition 7 relies on the following lemma.

Lemma 3. Suppose Assumptions 1 and 3 hold. Then $\tilde{V}^*(\cdot \mid f)$ is strictly increasing for every $f \in \mathcal{S}_p$, and the right hand side of (15) is strictly concave in $a$.

Proof. Define $Z(x) = 0$ for all $x$, and let $V_f^{(\ell)} = T_f Z$. Observe that if $V_f^{(\ell)}$ is nondecreasing, then under the conditions of the lemma, it follows that $V_f^{(\ell+1)}$ will be nondecreasing. Taking the limit as $n \to \infty$, we conclude (from convergence of value iteration) that $\tilde{V}^*(\cdot \mid f)$ is nondecreasing, and thus the right hand side of (15) is strictly increasing in $x$. From this it follows that in fact, $\tilde{V}^*(\cdot \mid f)$ is strictly increasing.

Since $\tilde{V}^*(\cdot \mid f)$ is strictly increasing, $\pi(x, a, f)$ is concave in $a$, and the kernel is stochastically concave in $a$, with at least one of the last two strictly concave, it follows that the right hand side of (15) is strictly concave in $a$. $\square$

Proof of Proposition 7. Under Assumptions 1 and 2, the optimal action in (15) can be shown to be unique (see [15]). It follows that $P(f)$ is a singleton.

From the preceding lemma, Assumptions 1 and 3 together also guarantee a unique optimal solution in the right hand side of (15), for every $x \in \mathcal{X}$. Thus under either of these conditions the optimal strategy given $f$ is unique, i.e., $P(f)$ is a singleton. The result follows by Proposition 6. $\square$

In the remainder of this appendix we focus on compactness of the image of $\Phi$. Throughout this appendix we suppose $\mathcal{X} = \mathbb{Z}_+^d$ and that Assumptions 1 and 4 are in effect.

Lemma 4. Given $x' \geq x$, $x, x' \in \mathcal{X}$, $a \in \mathcal{A}$, and $f \in \mathcal{S}$, there exists a probability space with random variables $\xi' \sim Q(\cdot \mid x', a, f)$, $\xi \sim Q(\cdot \mid x, a, f)$, such that $\xi' \leq \xi$ almost surely, and $x' + \xi' \geq x + \xi$ almost surely.

Proof. The proof uses a coupling argument. Let $U$ be a uniform random variable on $[0, 1]$. Let $F_\ell$ (resp., $F'_\ell$) be the cumulative distribution function of $Q_\ell(\cdot \mid x, a, f)$ (resp., $Q_\ell(\cdot \mid x', a, f)$), and let $G_\ell$ (resp., $G'_\ell$) be the cumulative distribution function of $P_\ell(\cdot \mid x, a, f)$ (resp., $P_\ell(\cdot \mid x', a, f)$). By Assumption 4, $P_\ell(\cdot \mid x, a, f)$ is stochastically nondecreasing in $x$, and $Q_\ell(\cdot \mid x, a, f)$ is stochastically nonincreasing in $x$. Thus for all $z$, $F_\ell(z) \leq F'_\ell(z)$, but for all $y$, $G_\ell(y) \geq G'_\ell(y)$; further, $G_\ell(y) = F_\ell(y - x_\ell)$ (and $G'_\ell(y) = F'_\ell(y - x'_\ell)$). Let $\xi_\ell = \inf[z_\ell: F_\ell(z_\ell) \geq U]$, and let $\xi'_\ell = \inf[z_\ell: F'_\ell(z_\ell) \geq U]$. Then $\xi_\ell \geq \xi'_\ell$ for all $\ell$, i.e., $\xi \geq \xi'$. Rewriting the definitions, we...
also have $x'_\ell + \xi'_\ell = \inf\{y\ell: F_\ell(y\ell - x'_\ell) \geq U\}$, and $x'_\ell + \xi'_\ell = \inf\{y\ell: F_\ell(y\ell - x'_\ell) \geq U\}$, i.e., $x'_\ell + \xi'_\ell = \inf\{y\ell: G_\ell(y\ell) \geq U\}$, and $x'_\ell + \xi'_\ell = \inf\{y\ell: G_\ell(y\ell) \geq U\}$. Thus $x'_\ell + \xi'_\ell \leq x'_\ell + \xi'_\ell$ for all $\ell$, i.e., $x' + \xi' \geq x + \xi$, as required. □

Given a set $S$ define $\rho_\infty(x, S) = \inf_{y \in S} \|x - y\|_\infty$. Thus $\rho_\infty$ gives the $\infty$-norm distance to a set. We have the following lemma.

**Lemma 5.** As $\|x\|_\infty \to \infty$, $\sup_{f \in S} \sup_{\mu \in \mathcal{P}(f)} \rho_\infty(\mu(x), A') \to 0$.

**Proof.** Suppose the statement of the lemma fails; then there exist $r > 0$ and a sequence $f_n \in S$, $\mu_n \in \mathcal{P}(f_n)$, and $x_n$ (where $\|x_n\|_\infty \to \infty$) such that $\rho_\infty(\mu_n(x_n), A') \geq r$ for all $n$. We use this fact to construct a profitable deviation from the policy $\mu_n$, for sufficiently large $n$.

Observe that by Assumption 4, there must exist $a'_n \in A'$ with $a'_n \leq \mu_n(x_n)$, such that:

$$\pi(x_n, a'_n, f_n) - \pi(x_n, \mu_n(x_n), f_n) \geq \kappa\left(\|a'_n - \mu_n(x_n)\|_\infty\right) \geq \kappa(r) > 0,$$

where the last inequality follows since $\kappa$ is strictly increasing with $\kappa(0) = 0$. Importantly, note the bound on the right hand side is a constant, independent of $n$.

Let $x_{0,n} = x_n$, and let $x_{i,n}$ and $a_{i,n}$ denote the state and action sequence realized under $\mu_n$, starting from $x_{0,n}$, under the kernel $P(\cdot | x, a, f_n)$. We consider a deviation from $\mu_n$, where at time 0, instead of playing $a_{0,n} = \mu_n(x_n)$, the agent plays $a'_{0,n} = a'_n$; and then at all times in the future, the agent follows the same actions as the original sequence, i.e., $a'_{i,n} = a_{i,n}$. Let $x'_{i,n}$ denote the resulting state sequence.

Since the kernel is stochastically nondecreasing in $a$, and $a'_{n} \leq a_{n}$, it follows that there exists a common probability space together with increments $\xi_{0,n}$, $\xi'_{0,n}$, such that $\xi_{0,n} \sim Q(\cdot | x_n, a_n, f_n)$, $\xi'_{0,n} \sim Q(\cdot | x_n, a'_n, f_n)$, and $\xi'_{0,n} \leq \xi_{0,n}$ almost surely. Thus we can couple together $x_{1,n}$ and $x'_{1,n}$, by letting $x_{1,n} = x_n + \xi_{0,n}$, and $x'_{1,n} = x_n + \xi'_{0,n}$. In particular, observe that with these definitions we have $x_{1,n} \geq x'_{1,n}$. Let $\Delta_n = \xi_{0,n} - \xi'_{0,n} \geq 0$. Note that $|\Delta_n| \leq M$, by Assumption 1 (bounded increments).

Next, it follows from Lemma 4 that there exists a probability space with random variables $\xi_{1,n}$, $\xi'_{1,n}$ such that $\xi_{1,n} \sim Q(\cdot | x_{1,n}, a_{1,n}, f_n)$ and $\xi'_{1,n} \sim Q(\cdot | x'_{1,n}, a_{1,n}, f_n)$, $\xi_{1,n} \leq \xi'_{1,n}$ almost surely, and yet $x_{1,n} + \xi_{1,n} \geq x'_{1,n} + \xi'_{1,n}$ almost surely. Thus we can couple together $x_{2,n}$ and $x'_{2,n}$, by letting $x_{2,n} = x_{1,n} + \xi_{1,n}$, and let $x'_{2,n} = x'_{1,n} + \xi'_{1,n}$. Proceeding inductively, it can be shown that there exists a joint probability measure under which $0 \leq x_{t,n} - x'_{t,n} \leq \Delta_n$, almost surely, for all $t \geq 1$ (where the inequalities are interpreted coordinatewise); this follows by a standard application of the Kolmogorov extension theorem.

We now compare the payoffs obtained under these two sequences. We have:

$$E\left[\sum_{t} \beta^t \left(\pi(x_{1,n}, a_{1,n}, f_n) - \pi(x'_{1,n}, a'_{1,n}, f_n)\right)\right]$$

$$= \pi(x_n, \mu_n(x_n), f_n) - \pi(x_n, a'_n, f_n) + E\left[\sum_{t \geq 1} \beta^t \left(\pi(x_{1,n}, a_{1,n}, f_n) - \pi(x'_{1,n}, a'_{1,n}, f_n)\right)\right]$$

$$\leq -\kappa(r) + E\left[\sum_{t \geq 1} \beta^t \sup_{\delta \geq 0, \|\delta\|_\infty \leq 2M} \sup_{a, f} \left(\pi(x_{1,n}, a, f) - \pi(x_{1,n} - \delta, a, f)\right)\right].$$

Since increments are bounded (Assumption 4), in time $t$, the maximum distance the state could have moved in each coordinate from the initial state $x$ is bounded by $tM$. Thus if $x_{0,n} = x_n$, then:

$$
\sup_{\delta \geq 0} \sup_{\|\delta\|_{\infty} \leq 2M} (\pi(x_{t,n}, a, f) - \pi(x_{t,n} - \delta, a, f))
$$

$$
\leq \sup_{\delta \geq 0, \epsilon; \|\delta\|_{\infty} \leq 2M} \sup_{\|\epsilon\|_{\infty} \leq tM} (\pi(x_n + \epsilon, a, f) - \pi(x_n + \epsilon - \delta, a, f)).
$$

Let $A_{t,n}$ denote the right hand side of the preceding equation; note that this is a deterministic quantity, and that the supremum is over a finite set. Thus from Assumption 4, we have $\limsup_{n \to \infty} A_{t,n} \leq 0$.

Finally, observe that since $\limsup_{|x|_{\infty} \to \infty} \sup_{a,f} (\pi(x + \delta, a, f) - \pi(x, a, f)) \leq 0$, it follows that:

$$
\sup_{y \in \mathbb{Z}^d_{+}, \delta \geq 0; \|\delta\|_{\infty} \leq 2M} \sup_{a,f} (\pi(y, a, f) - \pi(y - \delta, a, f)) < \infty.
$$

We denote the left hand side of the preceding inequality by $D$. Note that this is a constant independent of $n$.

Combining our arguments, we have that for all sufficiently large $n$, there holds:

$$
\mathbb{E} \left[ \sum_t \beta^t \left( \pi(x_{t,n}, a_{t,n}, f_n) - \pi(x'_{t,n}, a'_{t,n}, f_n) \right) \right] \leq -\kappa(r) + \sum_{t=1}^T \beta^t A_{t,n} + \frac{\beta^T D}{1 - \beta}.
$$

By taking $T$ sufficiently large, we can ensure that the last term on the right hand side is strictly less than $\kappa(r)/2$; and by then taking $n$ sufficiently large, we can ensure that the second term on the right hand side is also strictly less than $\kappa(r)/2$. Thus for sufficiently large $n$, we conclude that the left hand side is negative—contradicting optimality of $\mu_n$. The lemma follows. \qed

**Lemma 6.** There exists $\bar{\epsilon} > 0$ and $\bar{R}$ such that for all $\ell$ and all $x$ with $x_\ell \geq \bar{R}$, $\sup_{f} \sup_{\mu \in \mathcal{P}(f)} \sum_{z_\ell} z_\ell \mathbb{E}[z_\ell | x, \mu(x), f] < -\bar{\epsilon}$.

**Proof.** Fix $\epsilon > 0$ so that for all $\ell$ and all $x'$ with $x'_\ell \geq K'$, $\sup_{a' \in \mathcal{A}} \sup_{f} \sum_{z_\ell} z_\ell \mathbb{E}[z_\ell | x', a', f] < -\epsilon$; such a constant exists by the last part of Assumption 4. Observe that since $\mathcal{A}$ is compact and $\sup_{f} \sum_{z_\ell} z_\ell \mathbb{E}[z_\ell | x, a, f]$ is continuous in $a$ (Assumption 4), it follows that $\sup_{f} \sum_{z_\ell} z_\ell \mathbb{E}[z_\ell | x, a, f]$ is in fact uniformly continuous in $a \in \mathcal{A}$. Let $e^{(\ell)}$ denote the $\ell$th standard basis vector (i.e., $e^{(\ell)} = 0$ for $\ell' \neq \ell$, and $e^{(\ell)} = 1$). By uniform continuity, we can conclude there must exist a $\delta_\ell > 0$ such that if $\|a - a'\|_{\infty} < \delta_\ell$, then:

$$
\left| \sup_{f} \sum_{z_\ell} z_\ell \mathbb{E}[z_\ell | K' e^{(\ell)} , a , f] - \sup_{f} \sum_{z_\ell} z_\ell \mathbb{E}[z_\ell | K' e^{(\ell)} , a', f] \right| < \epsilon/2.
$$

Note in particular, if $\rho_\infty(a, \mathcal{A}') < \delta_\ell$, then there exists $a' \in \mathcal{A}'$ with $\|a - a'\|_{\infty} < \delta_\ell$. By our choice of $\epsilon$ we have $\sup_{f} \sum_{z_\ell} z_\ell \mathbb{E}[z_\ell | K' e^{(\ell)} , a , f] < -\epsilon/2$. Now let $\delta = \min\{\delta_1, \ldots, \delta_d\}$. Since the increment kernel is stochastically nonincreasing in $x$, it follows that if $\rho_\infty(a, \mathcal{A}') < \delta$ and $x_\ell \geq K'$, then $\sup_{f} \sum_{z_\ell} z_\ell \mathbb{E}[z_\ell | x, a, f] < -\epsilon/2$. Since $\sup_{f} \sup_{\mu \in \mathcal{P}(f)} \rho_\infty(\mu(x), \mathcal{A}') \to 0$ as $\|x\|_{\infty} \to \infty$, the result follows if we let $\bar{\epsilon} = \epsilon/2$. \qed
Lemma 7. For every $f \in \mathfrak{F}$, $\Phi(f)$ is nonempty.

Proof. As described in the discussion of Section 5.3, it suffices to show that the state Markov chain induced by an optimal oblivious strategy possesses at least one invariant distribution—i.e., that $\mathcal{D}(\mu, f)$ is nonempty, where $\mu$ is an optimal oblivious strategy given $f$.

We first show that for every $f$ and every $\mu \in \mathcal{P}(f)$, the Markov chain on $\mathcal{X}$ induced by $\mu$ and $f$ has at least one closed class. Let $S = \{x \in \mathcal{X} : \|x\|_\infty \leq \overline{K} + M\}$. By Lemma 6, if $x \notin S$, then there exists some state $x'$ with $\mathbf{P}(x'\mid x, \mu(x), f) > 0$ such that $x'_\ell \leq x_\ell - \varepsilon$ for all $\ell$ where $x_\ell > \overline{K}$. On the other hand, since increments are bounded, for any $\ell$ where $x_\ell \leq \overline{K}$, we have $x'_\ell \leq \overline{K} + M$. Applying this fact inductively, we find that for any $x \notin S$, there must exist a positive probability sequence of states from $x$ to $S$; i.e., a sequence $y_0, y_1, y_2, \ldots, y_\tau$ such that $y_0 = x$, $y_\tau \in S$, and $\mathbf{P}(y_t \mid y_{t-1}, \mu(y_{t-1}), f) > 0$ for all $t$. We say that $S$ is reachable from $x$.

So now suppose the chain induced by $\mu$ and $f$ has no closed class. Fix $x_0 \in S$. Since the class containing $x_0$ is not closed, there must exist a state $x'$ reachable from $x_0$ with positive probability, such that the chain never returns to $x_0$ starting from $x'$. If $x' \in S$, let $x_1 = x'$. If $x' \notin S$, then using the argument in the preceding paragraph, there must exist a state $x_1 \in S$ reachable from $x'$. Arguing inductively, we can construct a sequence of states $x_0, x_1, x_2, \ldots$ where $x_t \in S$ for all $t$, and yet $x_0, \ldots, x_{t-1}$ are not reachable from $x_t$.

To complete the proof, we use a Foster–Lyapunov argument. Let $U(x) = \sum_\ell x_\ell^2$. Then $\{x \in \mathcal{X} : U(x) \leq R\}$ is finite for all $R$. So now let $\omega = (2d\overline{K}M + dM^2 + 1)/(2\varepsilon)$, and suppose $\|x\|_\infty > \max\{\omega, \overline{K}\}$. We reason as follows:

$$
\sum_{x'} U(x') \mathbf{P}(x'\mid x, \mu(x), f) = U(x) + 2 \sum_\ell x_\ell \sum_{z_\ell} Q_\ell(z_\ell\mid x, \mu(x), f) + \sum_\ell \sum_{z_\ell} z_\ell^2 Q_\ell(z_\ell\mid x, \mu(x), f) \\
\leq U(x) + 2 \sum_{\ell : x_\ell \leq \overline{K}} Mx_\ell - 2 \sum_{\ell : x_\ell > \overline{K}} \varepsilon x_\ell + dM^2 \leq U(x) - 1.
$$

The first equality follows by definition of $Q$ and $U$, and multiplicative separability of $Q$. The next step follows since increments are bounded (Assumption 4), and by applying Lemma 6 for $x_\ell > \overline{K}$. The last inequality follows from the fact that the state space is $d$-dimensional, $\|x\|_\infty > \max\{\overline{K}, \omega\}$, and by definition of $\omega$. Since increments are bounded, it is trivial that for every $R$:

$$
\sup_{x : \|x\|_\infty \leq \overline{K}} \left( \sum_{x'} U(x') \mathbf{P}(x'\mid x, \mu(x), f) - U(x) \right) < \infty.
$$

It follows by the Foster–Lyapunov criterion that every closed class of the Markov chain induced by $\mu$ is positive recurrent, as required [25,37,23]. \qed

The following lemma uses a Foster–Lyapunov argument as well, in a spirit similar to the proof of the preceding lemma; we omit the details. The interested reader is referred to the longer version of our paper [3].

Lemma 8. For every $\eta \in \mathbb{Z}_+$, $\sup_f \sup_{\phi \in \Phi(f)} \sum_{x} \|x\|^{\eta}_\Phi(x) < \infty$. 
Proof of Proposition 9. We have already established that $\Phi(f)$ is nonempty for all $f \in \mathfrak{F}$ in Lemma 7. Define $B = \sup_{f} \sup_{\phi \in \Phi(f)} \sum\limits_{x} x^{p+1} \phi(x) < \infty$, where the inequality is the result of Lemma 8.

We define the set $C = \{ f \in \mathfrak{F} : \sum\limits_{x} x^{p+1} f(x) \leq B \}$. By the preceding observation, $\Phi(\mathfrak{F}) \subset C$. It is clear that $C$ is nonempty and convex. It remains to be shown that $C$ is compact in the $1-p$ norm. It is straightforward to check that $C$ is complete; we show that $C$ is totally bounded, thus establishing compactness.

Fix $\epsilon > 0$. Choose $K_\epsilon$ so that $B/K_\epsilon < \epsilon$. Then for all $f \in C$:

$$\sum\limits_{x : \|x\|_{\infty} \geq K_\epsilon} x^{p} f(x) \leq B < \epsilon.$$ (16)

Let $S_\epsilon = \{ x : \|x\|_{\infty} < K_\epsilon \}$ and let $\mathcal{S}_C$ be the projection of $C$ onto $S_\epsilon$; i.e.,

$$\mathcal{S}_C = \{ g \in \mathbb{R}^{S_\epsilon} : \exists f \in C \text{ with } g(x) = f(x) \ \forall x \in S_\epsilon \}.$$

It is straightforward to check that $\mathcal{S}_C$ is a compact subset of the finite-dimensional space $\mathbb{R}^{S_\epsilon}$; so let $f_1, \ldots, f_k \in \mathcal{S}_C$ be a $\epsilon$-cover of $\mathcal{S}_C$ (i.e., $\mathcal{S}_C$ is covered by the balls around $f_1, \ldots, f_k$ of radius $\epsilon$ in the $1-p$ norm). Then it follows that $f_1, \ldots, f_k$ is a $2\epsilon$-cover of $C$, since (16) bounds the tail of any $f \in C$ by $\epsilon$. This establishes that $C$ is totally bounded in the $1-p$ norm, as required.

Appendix E. AME: proof

Throughout this appendix we suppose Assumption 1 holds. We begin by defining the following sets.

Definition 12. For every $x \in \mathcal{X}$, define

$$\mathcal{X}_x = \{ z \in \mathcal{X} \mid P(x \mid z, a, f) > 0 \text{ for some } a \in A \text{ and for some } f \in \mathfrak{F}_p \}.$$ (17)

Also define $\mathcal{X}_{x,t}$ as

$$\mathcal{X}_{x,t} = \{ z \in \mathcal{X} \mid \|z\|_{\infty} \leq \|x\|_{\infty} + tM \}.$$ (18)

Thus, $\mathcal{X}_x$ is the set of all initial states that can result in the final state as $x$. Since the increments are bounded (Assumption 1), for every $x \in \mathcal{X}$, the set $\mathcal{X}_x$ is finite. The set $\mathcal{X}_{x,t}$ is a superset of all possible states that can be reached at time $t$ starting from state $x$ (since the increments are uniformly bounded over action $a$ and distribution $f$); note that $\mathcal{X}_{x,t}$ is finite as well.

The following key lemma establishes that as the number of players grows large, the population empirical distribution in a game with finitely many players approaches the limiting SE population. The result is similar in spirit to related results on mean field limits of interacting particle systems, cf. [43]; there the main insight is that, under appropriate conditions, the stochastic evolution of a finite-dimensional interacting particle system approaches the deterministic mean field limit over finite time horizons. Our model introduces two sources of complexity. First, agents’ state transitions are coupled, so the population state Markov process is not simply the aggregation of independent agent state dynamics. Second, our state space is unbounded, so additional care is required to ensure the tail of the population state distribution is controlled in games with a large but finite number of players. This is where the light-tail condition plays a key role. Our proof proceeds by induction over time periods.
Lemma 9. Let \((\mu, f)\) be a stationary equilibrium with \(f \in \mathbb{F}_p\). Consider an \(m\)-player game. Let \(x_{i,0}^{(m)} = x_0\) and suppose the initial state of every player (other than player \(i\)) is independently sampled from the distribution \(f\). That is, suppose \(x_{j,0}^{(m)} \sim f\) for all \(j \neq i\); let \(f^{(m)} \in \mathbb{F}^{(m)}\) denote the initial population state. Let \(a_{i,t}^{(m)}\) be any sequence of (possibly random, possibly history dependent) actions. Suppose players’ states evolve as \(x_{i,t+1}^{(m)} \sim P(\cdot | x_{i,t}^{(m)}, a_{i,t}^{(m)}, f^{(m)} - i,t)\) and for all \(j \neq i\), as \(x_{j,t+1}^{(m)} \sim P(\cdot | x_{j,t}^{(m)}, \mu(x_{j,t}^{(m)}), f^{(m)} - j,t)\). Then, for every initial state \(x_0\), for all times \(t\), 
\[\|f^{(m)} - f\|_{1-p} \to 0\text{ almost surely}\]

Proof. Note that \(f \in \mathbb{F}_p\) and hence \(\|f\|_{1-p} < \infty\). Thus, given any \(\epsilon > 0\), there exists a finite set \(C_{\epsilon, f}\) such that:
\[\sum_{x \notin C_{\epsilon, f}} \|x\|_p^p f(x) < \epsilon.\] \(19\)

At \(t = 0\), we have
\[f_{-i,0}^{(m)}(x) = \frac{1}{m-1} \sum_{j=1}^{m-1} \mathbf{1}_{\{X_{j,0} = x\}},\]
where \(X_{j,0}\) are i.i.d. random variables distributed according to the distribution \(f\). Define:
\[Y_j = \|X_{j,0}\|_p^p \mathbf{1}_{\{X_{j,0} \notin C_{\epsilon, f}\}}.\]
Note that the \(Y_j\) are i.i.d. random variables, with:
\[E[Y_j] = \sum_{x \notin C_{\epsilon, f}} \|x\|_p^p f(x).\]

Further, observe that:
\[\sum_{x \notin C_{\epsilon, f}} \|x\|_p^p f_{-i,0}^{(m)}(x) = \frac{1}{m-1} \sum_{j=1}^{m-1} Y_j.\]

Thus by the strong law of large numbers, almost surely as \(m \to \infty\),
\[\sum_{x \notin C_{\epsilon, f}} \|x\|_p^p f_{-i,0}^{(m)}(x) \to \sum_{x \notin C_{\epsilon, f}} \|x\|_p^p f(x) < \epsilon.\]

Now observe that:
\[\|f_{-i,0}^{(m)}(x) - f\|_{1-p} \leq \sum_{x \in C_{\epsilon, f}} \|x\|_p^p f_{-i,0}^{(m)}(x) - f(x) + \sum_{x \notin C_{\epsilon, f}} \|x\|_p^p f_{-i,0}^{(m)}(x) + \sum_{x \notin C_{\epsilon, f}} \|x\|_p^p f(x).\]

Each of the second and third terms on the right hand side is almost surely less than \(\epsilon\) for sufficiently large \(m\). For the first term, observe that \(|f_{-i,0}^{(m)}(x) - f(x)| \to 0\text{ almost surely}\), again by

\[\text{Note that the convergence is almost surely in the randomness associated with the initial population state.}\]
the strong law of large numbers (since $f^{(m)}(x)$ is the sample average of $m - 1$ Bernoulli random variables with parameter $f(x)$). Thus the first term approaches zero almost surely as $m \to \infty$ by the bounded convergence theorem. Since $\epsilon$ was arbitrary, this proves that $\|f^{(m)}_{-i,0} - f\|_{1-p} \to 0$ almost surely as $m \to \infty$.

We now use an induction argument; let us assume that, $\|f^{(m)}_{-i,\tau} - f\|_{1-p} \to 0$ almost surely as $m \to \infty$ for all times $\tau \leq t$. From the definition of $f^{(m)}_{-i,t+1}$ we have:

$$f^{(m)}_{-i,t+1}(y) = \frac{1}{m - 1} \sum_{j \neq i} \sum_{x \in X} \{y^{(m)}_{j,i+1} = y\},$$

where $x^{(m)}_{j,i+1} \sim P(\cdot | x^{(m)}_{j,i}, \mu(x^{(m)}_{j,i}, f^{(m)}_{-j,i}))$ for all $j \neq i$. Note that if two players have same initial state, then the population state from their viewpoint is identical. That is, if $x^{(m)}_{j,i} = x^{(m)}_{k,i}$, then $f^{(m)}_{-j,i}(y) = f^{(m)}_{-k,i}(y)$ for all $y \in X$. We can thus redefine the population state from the viewpoint of a player at a particular state. Let $f^{(m)}_{t(x,m)}$ be the population state at time $t$ from the viewpoint of a player at state $x$. Then, if $x^{(m)}_{j,i} = x^{(m)}_{k,i} = x$, then for all $y \in X$, $f^{(m)}_{-j,i}(y) = f^{(m)}_{-k,i}(y) = f^{(m)}_{t(x,m)}(y)$. Without loss of generality, we assume $m > 1$. Let $\eta^{(m)}_{-i,t}(x)$ be the total number of players (excluding player $i$) that have their state at time $t$ as $x$, i.e., $\eta^{(m)}_{-i,t}(x) = (m - 1) f^{(m)}_{-i,t}(x)$. Note that $\eta^{(m)}_{-i,t}(x) = 0$ if and only if $f^{(m)}_{-i,t}(x) = 0$. We can now write $f^{(m)}_{-i,t+1}$ as:

$$f^{(m)}_{-i,t+1}(y) = \frac{1}{m - 1} \sum_{x \in X} \sum_{j = 1}^{\eta^{(m)}_{-i,t}(x)} 1_{\{y^{(m)} = y\}}$$

$$= \sum_{x \in X} f^{(m)}_{-i,t}(x) \left[ \frac{1}{\eta^{(m)}_{-i,t}(x)} \sum_{j = 1}^{\eta^{(m)}_{-i,t}(x)} 1_{\{y^{(m)} = y\}} \right]$$

$$= \sum_{x \in X} f^{(m)}_{-i,t}(x) \left[ \frac{1}{\eta^{(m)}_{-i,t}(x)} \sum_{j = 1}^{\eta^{(m)}_{-i,t}(x)} 1_{\{y^{(m)} = y\}} \right]$$

where the last equality follows from Definition 12. Here, $Y^{(m)}_{j,x,t}$ are random variables that are independently drawn according to the transition kernel $P(\cdot | x, \mu(x), \hat{f}^{(x,m)}_{t})$. Note that if $\eta^{(m)}_{-i,t}(x) = 0$, we interpret the term inside the parentheses as zero.

Let us now look at $\hat{f}^{(x,m)}_{t}$. We have

$$\hat{f}^{(x,m)}_{t}(z) = f^{(m)}_{-i,t}(z) + \frac{1}{m - 1} \{x^{(m)}_{i,t} = z\} - \frac{1}{m - 1} \{z = x\}.$$
From the induction hypothesis, we have \( \| f_{-i,t}^{(m)} \|_{1-p} \to 0 \) almost surely as \( m \to \infty \). Note that at time \( t \), \( x_{i,t}^{(m)} \in X_{x_{0,t}} \) from Eq. (18), and \( X_{x_{0,t}} \) is finite. Thus,

\[
\sup_m \sum_{z \in \mathcal{X}} \| z \|_p^p 1_{\{x_{i,t}^{(m)} = z\}} \leq 0, \quad \text{almost surely.}
\]

This implies that for all states \( x \in \mathcal{X} \), \( \| f_{-i,t}^{(x,m)} \|_{1-p} \to 0 \) almost surely as \( m \to \infty \). From Assumption 1, we know that the transition kernel is continuous in the population state \( f \) (where \( \mathfrak{F}_p \) is endowed with the 1-\( p \) norm). Thus for every \( x \in \mathcal{X} \), we have almost surely:

\[
P\left( \cdot \mid x, \mu(x), f_{-i,t}^{(x,m)} \right) \to P\left( \cdot \mid x, \mu(x), f \right), \quad (21)
\]

as \( m \to \infty \).

Next, we show that \( f_{-i,t+1}^{(m)}(y) \to f(y) \) almost surely as \( m \to \infty \), for all \( y \). We leverage Eq. (20). Observe that the set of points \( x \in \mathcal{X} \) where \( \| x \|_p \leq 1 \) is finite, since \( \mathcal{X} \) is a subset of an integer lattice. From the induction hypothesis, as \( \sum_{x \in \mathcal{X}} \| x \|_p | f_{-i,t}^{(m)}(x) - f(x) | \to 0 \) almost surely as \( m \to \infty \), it follows that \( f_{-i,t}^{(m)}(x) \to f(x) \) almost surely for all \( x \in \mathcal{X} \) as \( x \to \infty \).

Suppose that \( x \in \mathcal{X}_x \) and \( f(x) > 0 \). Since \( f_{-i,t}^{(m)}(x) \to f(x) \), it follows that \( \eta_{-i,t} \to \infty \) as \( m \to \infty \), almost surely. Note that \( Y_{j,x,t}^{(m)} \) are random variables that are independently drawn according to the transition kernel \( P(\cdot \mid x, \mu(x), f_{-i,t}^{(x,m)}) \). From Eq. (21), and Lemma 10, we get that for every \( x, y \in \mathcal{X} \), there holds

\[
\frac{1}{\eta_{-i,t}^{(m)}(x)} \sum_{j=1}^{\eta_{-i,t}^{(m)}(x)} 1_{\{Y_{j,x,t}^{(m)} = y\}} \to P(y \mid x, \mu(x), f),
\]

almost surely as \( m \to \infty \).

On the other hand, suppose \( x \in \mathcal{X}_y \) and \( f(x) = 0 \). Again, since \( f_{-i,t}^{(m)}(x) \to f(x) \) as \( x \to \infty \), it follows that as \( m \to \infty \), almost surely:

\[
f_{-i,t}^{(m)}(x) \left[ \frac{1}{\eta_{-i,t}^{(m)}(x)} \sum_{j=1}^{\eta_{-i,t}^{(m)}(x)} 1_{\{Y_{j,x,t}^{(m)} = y\}} \right] \to 0,
\]

since the term in brackets is nonnegative and bounded. (Recall we interpret the term in brackets as zero if \( f_{-i,t}^{(m)}(x) = 0 \).)
We conclude that, almost surely, as \( m \to \infty \):

\[
\begin{align*}
    f^{(m)}_{-i,t+1}(y) &= \sum_{x \in X} f^{(m)}_{-i,t}(x) \left[ \frac{1}{\eta^{(m)}_{-i,t}(x)} \sum_{j=1}^{\eta^{(m)}_{j,i,t}(x)} 1_{y^{(m)}_{j,i,t}(x) = y} \right] \\
    &\rightarrow \sum_{x \in X} f(x)p(y | x, \mu(x), f) = f(y).
\end{align*}
\]

To complete the proof, we need to show that \( \| f^{(m)}_{-i,t+1} - f \|_1 \to 0 \) almost surely as \( m \to \infty \). Since \( f^{(m)}_{-i,t}(x) \to f(x) \) almost surely, for all \( \epsilon > 0 \) we have:

\[
\sum_{x \in C_{\epsilon,f}} \| x \|_p f^{(m)}_{-i,t}(x) \to \sum_{x \in C_{\epsilon,f}} \| x \|_p f(x).
\]

This together with the fact that \( \| f^{(m)}_{-i,t} - f \|_1 \to 0 \) implies that, almost surely:

\[
\limsup_{m \to \infty} \sum_{x \in C_{\epsilon,f}} \| x \|_p f^{(m)}_{-i,t}(x) < \epsilon.
\]

Now at time \( t + 1 \), we have

\[
\sum_{x \notin C_{\epsilon,f}} \| x \|_p f^{(m)}_{-i,t+1} = \sum_{x \notin C_{\epsilon,f}} \sum_{\ell=1}^{d} |x_\ell|^p f^{(m)}_{-i,t+1}(x) \\
\leq \sum_{x \notin C_{\epsilon,f}} \sum_{\ell=1}^{d} (|x_\ell| + M)^p f^{(m)}_{-i,t}(x),
\]

where the equality follows because \( X \) is a subset of the \( d \)-dimensional integer lattice. The last inequality follows from the fact that the increments are bounded (Assumption 1). Without loss of generality, assume that \( |x_\ell| \geq 1 \) and that \( M \geq 1 \). Then we have:

\[
(|x_\ell| + M)^p = \sum_{j=1}^{p} \binom{p}{j} |x_\ell|^j M^{p-j} \\
\leq \sum_{j=1}^{p} \binom{p}{j} |x_\ell|^j M^p \\
= 2^p M^p |x_\ell|^p = K_1 |x_\ell|^p,
\]

where we let \( K_1 = (2M)^p \). Substituting in Eq. (23), we have, almost surely,

\[
\limsup_{m \to \infty} \sum_{x \notin C_{\epsilon,f}} \| x \|_p f^{(m)}_{-i,t+1} \leq \sum_{x \notin C_{\epsilon,f}} \sum_{\ell=1}^{d} K_1 |x_\ell|^p f^{(m)}_{-i,t}(x) \\
= K_1 \sum_{x \notin C_{\epsilon,f}} \| x \|_p f^{(m)}_{-i,t}(x) \\
< K_1 \epsilon,
\]

where the last inequality follows from Eq. (22). Now observe that:
In taking a limsup on the left hand side, the second term on the right hand side is almost surely less than $K_1 \epsilon$. From the definition of $C_{\epsilon,f}$ and Eq. (19), we get that the third term on the right hand side is also less than $\epsilon$. Finally, since for every $x |f_{m}^{(m)}(x) - f(x)| \rightarrow 0$ almost surely as $m \rightarrow \infty$, and $C_{\epsilon,f}$ is finite, the first term in the above equation approaches zero almost surely as $m \rightarrow \infty$ by the bounded convergence theorem. Since $\epsilon$ was arbitrary, this proves the induction step and hence the lemma. \hfill \Box

The preceding proof uses the following refinement of the strong law of large numbers.

**Lemma 10.** Suppose $0 \leq p_k \leq 1$ for all $k$, and that $p_k \rightarrow p$ as $k \rightarrow \infty$. For each $k$, let $Y^{(k)}_1, \ldots, Y^{(k)}_k$ be i.i.d. Bernoulli random variables with parameter $p_k$. Then almost surely:

$$\lim_{k \rightarrow \infty} \frac{1}{k} \sum_{i=1}^{k} Y^{(k)}_i = p.$$  

**Proof.** Let $\epsilon > 0$. By Hoeffding’s inequality, we have:

$$\text{Prob} \left( \left| \frac{1}{k} \sum_{i=1}^{k} Y^{(k)}_i - p_k \right| > \epsilon \right) \leq 2e^{-k\epsilon^2},$$

since $0 \leq Y^{(k)}_i \leq 1$ for all $i, k$. Let $\epsilon_k = 1/k$; then by the Borel–Cantelli lemma, the event on the left hand side in the preceding expression occurs for only finitely many $k$, almost surely. In other words, almost surely:

$$\lim_{k \rightarrow \infty} \left[ p_k - \frac{1}{k} \sum_{i=1}^{k} Y^{(k)}_i \right] = 0.$$  

The result follows. \hfill \Box

Before we prove the AME property, we need some additional notation. Let $(\mu, f)$ be an SE. Consider again an $m$ player game and focus on player $i$. Let $x^{(m)}_{i,0} = x_0$ and assume that player $i$ uses a cognizant strategy $\mu_m$. The initial state of every other player $j \neq i$ is independently drawn from the distribution $f$, that is, $x^{(m)}_{j,0} \sim f$. Denote the initial distribution of all $m - 1$ players (excluding player $i$) by $f^{(m)}(m) \in \mathcal{F}^{(m)}$. The state evolution of player $i$ is given by

$$x^{(m)}_{i,t+1} \sim P(\cdot | x^{(m)}_{i,t}, a^{(m)}_{i,t}, f^{(m)}_{i,t}),$$

where $a^{(m)}_{i,t} = \mu_m(x^{(m)}_{i,t}, f^{(m)}_{i,t})$ and $f^{(m)}_{i,t}$ is the actual population distribution. Here the superscript $m$ on the state variable represents the fact that we are considering an $m$ player stochastic game. Let every other player $j$ use the oblivious strategy $\mu$ and thus their state evolution is given by
\[ x_{i,t+1}^{(m)} \sim \mathbf{P} (\cdot \mid x_{i,t}^{(m)}, \mu (x_{i,t}^{(m)}, I_{-i,t}^{(m)})). \]  

(25)

Define \( V^m (x, f | \mu_m, \mu^{(m-1)}) \) to be the actual value function of player \( i \), with its initial state \( x \), the initial distribution of the rest of the population as \( f^{(m)} \in S^{(m)} \), when the player uses a cognizant strategy \( \mu_m \) and every other player uses an oblivious strategy \( \mu \). We have

\[
V^m (x, f | \mu_m, \mu^{(m-1)}) = \mathbb{E} \left[ \sum_{i=0}^{\infty} \beta^i \pi (x_{i,t}^{(m)}, \hat{a}_{i,t}^{(m)}, f^{(m)}_{-i,t}) \mid x_{i,0} = x, f_{-i,0}^{(m)} = f^{(m)}; \mu_i = \mu_m, \mu_{-i} = \mu^{(m-1)} \right].
\]

(26)

We define a new player that is coupled to player \( i \) in the \( m \) player stochastic games defined above. We call this player the coupled player. Let \( \hat{x}_{i,t}^{(m)} \) be the state of this coupled player at time \( t \). The subscript \( i \) and the superscript \( m \) reflect the fact that this player is coupled to player \( i \) in an \( m \) player stochastic game. We assume that the state evolution of this player is given by:

\[
\hat{x}_{i,t+1}^{(m)} \sim \mathbf{P} (\cdot \mid \hat{x}_{i,t}^{(m)}, \hat{a}_{i,t}^{(m)}, f),
\]

(27)

where \( \hat{a}_{i,t}^{(m)} = a_{i,t}^{(m)} = \mu_m (x_{i,t}^{(m)}, f^{(m)}_{-i,t}) \). In other words, this coupled player takes the same action as player \( i \) at every time \( t \) and this action depends on the actual population state of \( m - 1 \) players. However, note that the state evolution is dependent only on the mean field population state \( f \).

Let us define

\[
\hat{V}^m (x \mid f; \mu_m, \mu^{(m-1)}) = \mathbb{E} \left[ \sum_{i=0}^{\infty} \beta^i \pi (\hat{x}_{i,t}^{(m)}, \hat{a}_{i,t}^{(m)}, f) \mid \hat{x}_{i,0}^{(m)} = x, \hat{a}_{i,0}^{(m)} = \mu_m (x_{i,t}^{(m)}, f^{(m)}_{-i,t}); \mu^{(m-1)} \right].
\]

(28)

Thus, \( \hat{V}^m (x \mid f; \mu_m, \mu) \) is the expected net present value of this coupled player, when the player’s initial state is \( x \), the long run average population state is \( f \), and the initial population state is \( f_{-i,0}^{(m)} = f^{(m)} \). Observe that

\[
\hat{V}^m (x \mid f; \mu_m, \mu^{(m-1)}) \leq \sup_{\mu' \in \mathcal{O}} \hat{V}^m (x \mid f; \mu', \mu^{(m-1)})
\]

\[
= \sup_{\mu' \in \mathcal{O}} \hat{V}^m (x \mid f; \mu', \mu^{(m-1)})
\]

\[
= \overline{V}^* (x \mid f) = \overline{V} (x \mid \mu, f).
\]

(29)

Here, the first equality follows from Lemma 2, which implies that the supremum over all cognizant strategies is the same as the supremum over oblivious strategies (since the state evolution of other players does not affect the payoff of this coupled player), and the last equality follows since \( \mu \in \mathcal{O}(f) \).

**Lemma 11.** Let \( (\mu, f) \) be a stationary equilibrium and consider an \( m \) player game. Let the initial state of player \( i \) be \( x_{i,0}^{(m)} = x \), and let \( f^{(m)} \in S^{(m)} \) be the initial population state of \( m - 1 \) players whose initial state is sampled independently from the distribution \( f \). Assume that player \( i \) uses a cognizant strategy \( \mu_m \) and every other player uses the oblivious strategy \( \mu \). Their state evolutions are given by Eqs. (24) and (25). Also define a coupled player with initial state \( \hat{x}_{i,0}^{(m)} = x \) and let
its state evolution be given by Eq. (27). Then, for all times \( t \), and for every \( y \in X \), we have |
\[ \text{Prob}(x_{i,t}^{(m)} = y) - \text{Prob}(\hat{x}_{i,t}^{(m)} = y) \mid \to 0, \text{ almost surely} \]
as \( m \to \infty \).

**Proof.** The lemma is trivially true for \( t = 0 \). Let us assume that it holds for all times \( \tau = 0, 1, \ldots, t - 1 \). Then, we have
\[
\text{Prob}(x_{i,t}^{(m)} = y) = \sum_{z \in X_y} \text{Prob}(x_{i,t-1}^{(m)} = z) \mathcal{P}(y \mid z, \mu_m(z, f_{-i,t-1}^{(m)}, f^{(m)}_{-i,t-1})),
\]
and
\[
\text{Prob}(\hat{x}_{i,t}^{(m)} = y) = \sum_{z \in X_y} \text{Prob}(\hat{x}_{i,t-1}^{(m)} = z) \mathcal{P}(y \mid z, \mu_m(z, f_{-i,t-1}^{(m)}, f)).
\]
Here we use the fact that the coupled player uses the same action as player \( i \) and the state evolution of the coupled player is given by Eq. (27). Note that the summation is over all states in the finite set \( X_y \), where \( X_y \) is defined as in Eq. (17).

From Lemma 9, we know that for all times \( t \), \( \|f^{(m)}_{-i,t} - f\|_{1-p} \to 0 \) almost surely as \( m \to \infty \). From Assumption 1, we know that the transition kernel is jointly continuous in the action \( a \) and distribution \( f \) (where the set of distributions \( \mathcal{F}_p \) is endowed with \( 1-p \) norm). Since the action set is compact, this implies that for all \( y, z \in X \), \( \lim_{m \to \infty} \sup_{a \in A} |\mathcal{P}(y \mid z, a, f^{(m)}_{-i,t-1}) - \mathcal{P}(y \mid z, a, f)| = 0 \), almost surely. It follows that for every \( y, z \in X \), \( \lim_{m \to \infty} |\mathcal{P}(y \mid z, \mu_m(z, f^{(m)}_{-i,t-1}), f^{(m)}_{-i,t-1}) - \mathcal{P}(y \mid z, \mu_m(z, f^{(m)}_{-i,t-1}), f)| = 0 \) almost surely. From the induction hypothesis, we know that for every \( z \in X \), \( \text{Prob}(\hat{x}_{i,t-1}^{(m)} = z) - \text{Prob}(\hat{x}_{i,t-1}^{(m)} = z) \mid \to 0 \) almost surely as \( m \to \infty \). This along with the finiteness of the set \( X_y \), gives that for every \( y \in X \), \( \text{Prob}(\hat{x}_{i,t}^{(m)} = y) - \text{Prob}(x_{i,t}^{(m)} = y) \mid \to 0 \) almost surely as \( m \to \infty \). This proves the lemma. \( \square \)

**Lemma 12.** Let \( (\mu, f) \) be a stationary equilibrium and consider an \( m \) player game. Let the initial state of player \( i \) be \( x_{i,0} = x \), and let \( f^{(m)} \in \mathcal{F}^{(m)} \) be the initial population state of \( m - 1 \) players whose initial state is sampled independently from the distribution \( f \). Assume that player \( i \) uses a cognizant strategy \( \mu_m \) and every other player uses the oblivious strategy \( \mu \). Their state evolutions are given by Eqs. (24) and (25). Also define a coupled player with initial state \( \hat{x}_{i,0}^{(m)} = x \) and let its state evolution be given by Eq. (27). Then, for all times \( t \), we have \( \lim \sup_{m \to \infty} \mathbb{E}[\pi(x_{i,t}^{(m)}, \mu_m(x_{i,t}^{(m)}, f^{(m)}_{-i,t}), f^{(m)}_{-i,t}) - \pi(\hat{x}_{i,t}^{(m)}, \mu_m(x_{i,t}^{(m)}, f^{(m)}_{-i,t}), f)] \leq 0 \), almost surely.\(^{16}\)

**Proof.** Let us write \( a_{i,t}^{(m)} = \mu_m(x_{i,t}^{(m)}, f^{(m)}_{-i,t}) \). We have
\[
\Delta_{i,t}^{(m)} = \mathbb{E}[\pi(x_{i,t}^{(m)}, a_{i,t}^{(m)}, f^{(m)}_{-i,t}) - \pi(\hat{x}_{i,t}^{(m)}, a_{i,t}^{(m)}, f)]
\]
\[= \mathbb{E}[\pi(x_{i,t}^{(m)}, a_{i,t}^{(m)}, f^{(m)}_{-i,t}) - \pi(x_{i,t}^{(m)}, a_{i,t}^{(m)}, f)]
\]
\[+ \mathbb{E}[\pi(x_{i,t}^{(m)}, a_{i,t}^{(m)}, f) - \pi(\hat{x}_{i,t}^{(m)}, a_{i,t}^{(m)}, f)]
\]
\[\triangleq T_{1,t}^{(m)} + T_{2,t}^{(m)}. \]

\(^{15}\) The almost sure convergence of the probabilities is in the randomness associated with the initial population state.

\(^{16}\) The almost sure convergence of the expected value of the payoff is in the randomness associated with the initial population state.
Consider the first term. We have
\[
T^{(m)}_{1,t} \leq \sum_{y \in \mathcal{X}} \text{Prob}(x^{(m)}_{i,t} = y) \sup_{a \in \mathcal{A}} |\pi(y, a, f^{(m)}_{-i,t}) - \pi(y, a, f)|
\]
\[
= \sum_{y \in \mathcal{X}_{i,t}} \text{Prob}(x^{(m)}_{i,t} = y) \sup_{a \in \mathcal{A}} |\pi(y, a, f^{(m)}_{-i,t}) - \pi(y, a, f)|,
\]
where the last equality follows from the fact that \(x^{(m)}_{i,0} = x\) and from Eq. (18). From Assumption 1, we know that the payoff is jointly continuous in action \(a\) and distribution \(f\) (with the set of distributions \(\mathcal{F}_p\) endowed with \(\ell_1\) norm) and the set \(\mathcal{A}\) is compact. Thus, for every \(y \in \mathcal{X}\), we have \(\sup_{a \in \mathcal{A}} |\pi(y, a, f^{(m)}_{-i,t}) - \pi(y, a, f)| \to 0\), almost surely as \(m \to \infty\). This along with the fact that \(\mathcal{X}_{i,t}\) is finite shows that \(\limsup_{m \to \infty} T^{(m)}_{1,t} \leq 0\) almost surely.

Now consider the second term. We have
\[
T^{(m)}_{2,t} = \mathbb{E}[\pi(x^{(m)}_{i,t}, a^{(m)}_{i,t}, f) - (\hat{x}^{(m)}_{i,t}, a^{(m)}_{i,t}, f)]
\]
\[
\leq \sum_{y \in \mathcal{X}} |\text{Prob}(x^{(m)}_{i,t} = y) - \text{Prob}(\hat{x}^{(m)}_{i,t} = y)| \sup_{a \in \mathcal{A}} |\pi(y, a, f)|
\]
\[
= \sum_{y \in \mathcal{X}_{i,t}} |\text{Prob}(x^{(m)}_{i,t} = y) - \text{Prob}(\hat{x}^{(m)}_{i,t} = y)| \sup_{a \in \mathcal{A}} |\pi(y, a, f)|,
\]
where the last equality follows from the fact that \(\hat{x}^{(m)}_{i,0} = \tilde{x}^{(m)}_{i,0} = x\) and from Definition 12. From Lemma 11, we know that for every \(y \in \mathcal{X}\), \(|\text{Prob}(x^{(m)}_{i,t} = y) - \text{Prob}(\hat{x}^{(m)}_{i,t} = y)| \to 0\) almost surely \(m \to \infty\). Since \(\mathcal{X}_{i,t}\) is finite for every fixed \(x \in \mathcal{X}\) and every time \(t\), this implies that \(\limsup_{m \to \infty} T^{(m)}_{2,t} \leq 0\) almost surely. This proves the lemma. 

Before we proceed further, we need one additional piece of notation. Once again let \((\mu, f)\) be an SE and consider an oblivious player. Let \(\tilde{x}_t\) be the state of this oblivious player at time \(t\). We assume that \(\tilde{x}_0 = x\) and since the player used the oblivious strategy \(\mu\), the state evolution of this player is given by
\[
\tilde{x}_{t+1} \sim \mathcal{P}(\cdot \mid \tilde{x}_t, \tilde{a}_t, f)
\]
(30)
where \(\tilde{a}_t = \mu(\tilde{x}_t)\). We let \(\tilde{V}(x \mid \mu, f)\) (as defined in Eq. (7)) to be the oblivious value function for this player starting from state \(x\).

Also, consider an \(m\) player game and focus on player \(i\). We represent the state of player \(i\) at time \(t\) by \(\tilde{x}^{(m)}_{i,t}\). As before, the superscript \(m\) on the state variable represents the fact that we are considering an \(m\) player stochastic game. Let \(\tilde{x}^{(m)}_{i,0} = x\) and let player \(i\) also use the oblivious strategy \(\mu\). The initial state of every other player \(j \neq i\) is drawn independently from the distribution \(f\), that is, \(\tilde{x}^{(m)}_{j,0} \sim f\). Denote the initial distribution of all \(m-1\) players (excluding player \(i\)) by \(f^{(m)} \in \mathcal{F}^{(m)}\). The state evolution of player \(i\) is then given by
\[
\tilde{x}^{(m)}_{i,t+1} \sim \mathcal{P}(\cdot \mid \tilde{x}^{(m)}_{i,t}, \tilde{a}^{(m)}_{i,t}, f^{(m)}_{-i,t}),
\]
(31)
where \(\tilde{a}^{(m)}_{i,t} = \mu(\tilde{x}^{(m)}_{i,t})\). Note that even though the player uses an oblivious strategy, its state evolution is affected by the actual population state. Let every other player \(j\) also use the oblivious strategy \(\mu\) and let their state evolution be given by
\[ \tilde{x}^{(m)}_{j,i,t+1} \sim P(\cdot | \tilde{x}^{(m)}_{j,i,t}, \mu(\tilde{x}^{(m)}_{j,i}), f^{(m)}_{-j,i}). \]  

(32)

Define \( V^{(m)}(x, f^{(m)} | \mu^{(m)}) \) to be the actual value function of the player, when the initial state of the player is \( x \), the initial population distribution is \( f^{(m)} \) and every player uses the oblivious strategy \( \mu \). That is,

\[
V^{(m)}(x, f^{(m)} | \mu^{(m)}) = \mathbb{E}\left[ \sum_{t=0}^{\infty} \beta^t \pi(\tilde{x}_{i,t}, \tilde{a}_{i,t}, f^{(m)}_{-i,t}) \mid \tilde{x}_{i,0} = x, f^{(m)}_{-i,0} = f^{(m)}; \mu_i = \mu, \mu_{-i} = \mu^{(m)} \right].
\]

(33)

The proofs of the next two lemmas have similar arguments to Lemmas 11 and 12; we omit the details and refer the reader to the longer version of our paper [3].

Lemma 13. Let \((\mu, f)\) be a stationary equilibrium and consider an \( m \) player stochastic game. Let \( \tilde{x}_{i,0} = x \), and let \( f^{(m)} \in \mathcal{F}^{(m)} \) be the initial population state of \( m - 1 \) players whose initial state is sampled independently from \( f \). Assume that every player uses the oblivious strategy \( \mu \) and their state evolutions are given by Eqs. (31) and (32). Also, consider an oblivious player with \( \tilde{x}_0 = x \) and let its state evolution be given by Eq. (30). Then, for every time \( t \) and for all \( y \in \mathcal{X} \), we have \(|\text{Prob}(\tilde{x}_t = y) - \text{Prob}(\tilde{x}^{(m)}_{i,t} = y)| \to 0\), almost surely as \( m \to \infty \).

Lemma 14. Let \((\mu, f)\) be a stationary equilibrium and consider an \( m \) player stochastic game. Let \( \tilde{x}_{i,0} = x \), and let \( f^{(m)} \in \mathcal{F}^{(m)} \) be the initial population state of \( m - 1 \) players whose initial state is sampled independently from \( f \). Assume that every player uses the oblivious strategy \( \mu \) and their state evolutions are given by Eqs. (31) and (32). Also, consider an oblivious player with \( \tilde{x}_0 = x \) and let its state evolution be given by Eq. (30). Then for all times \( t \), we have \( \mathbb{E}[\pi(\tilde{x}_t, \mu(\tilde{x}_t), f) - \pi(\tilde{x}^{(m)}_{i,t}, \mu(\tilde{x}^{(m)}_{i,t}), f^{(m)}_{-i,t})] \to 0\), almost surely as \( m \to \infty \).

Proof of Theorem 2. Let us define

\[
\Delta V^{(m)}(x, f^{(m)}) \triangleq V^{(m)}(x, f^{(m)} | \mu_{m}, \mu^{(m-1)}) - V^{(m)}(x, f^{(m)} | \mu^{(m)}).
\]

Then we need to show that for all \( x \), \( \limsup_{m \to \infty} \Delta V^{(m)}(x, f^{(m)}) \leq 0 \) almost surely. We can write

\[
\Delta V^{(m)}(x, f^{(m)}) = V^{(m)}(x, f^{(m)} | \mu_{m}, \mu^{(m-1)}) - \tilde{V}(x | \mu, f) + \tilde{V}(x | \mu, f) - V^{(m)}(x, f^{(m)} | \mu^{(m)})
\]

\[
\leq V^{(m)}(x, f^{(m)} | \mu_{m}, \mu^{(m-1)}) - \tilde{V}^{(m)}(x | f; \mu_{m}, \mu^{(m-1)}) + \tilde{V}(x | \mu, f) - V^{(m)}(x, f^{(m)} | \mu^{(m)})
\]

\[
\triangleq T^{(m)}_1 + T^{(m)}_2.
\]

Here the inequality follows from Eq. (29). Consider the term \( T^{(m)}_1 \). We have

\[
T^{(m)}_1 = V^{(m)}(x, f^{(m)} | \mu_{m}, \mu^{(m-1)}) - \tilde{V}^{(m)}(x | f; \mu_{m}, \mu^{(m-1)})
\]

\[
= \mathbb{E}\left[ \sum_{i=0}^{\infty} \beta^t \pi(x^{(m)}_{i,t}, a^{(m)}_{i,t}, f^{(m)}_{-i,t}) - \pi(x^{(m)}_{i,t}, a^{(m)}_{i,t}, f) \right].
\]
where the last equality follows from Eqs. (26) and (28). Note that $x_{i,0} = \hat{x}_{i,0} = x$ and $a_{i,t} = \hat{a}_{i,t} = \mu_m(x_{i,t}, \hat{f}_{-i,t})$ and the state transitions of players are given by Eqs. (24), (25), and (27). From Lemma 12, we have $\lim \sup_{m \to \infty} E[\sum_{t=0}^{T-1} \beta^t (\pi(x_{i,t}^{(m)}, a_{i,t}^{(m)}, f^{(m)}) - \pi(\hat{x}_{i,t}^{(m)}, \hat{a}_{i,t}^{(m)}, f))] \leq 0$, almost surely for any finite time $T$. From Lemma 1, we have, almost surely

$$E[\sum_{t=T}^{\infty} \beta^t (\pi(x_{i,t}^{(m)}, a_{i,t}^{(m)}, f^{(m)}) - \pi(\hat{x}_{i,t}^{(m)}, \hat{a}_{i,t}^{(m)}, f))] \leq 2C(x, T),$$

which goes to zero as $T \to \infty$. This proves that $\lim \sup_{m \to \infty} T^{(m)}_1 \leq 0$ almost surely. Similar analysis (with an application of Lemma 14) shows that $\lim \sup_{m \to \infty} T^{(m)}_2 \leq 0$ almost surely, yielding the result. □
