Chapter 18

Piecewise-linear diffusion processes

Sid Browne and Ward Whitt

ABSTRACT  Diffusion processes are often regarded as among the more abstruse stochastic processes, but diffusion processes are actually relatively elementary, and, thus, are natural first candidates to consider in queueing applications. To help demonstrate the advantages of diffusion processes, we show that there is a large class of one-dimensional diffusion processes for which it is possible to give convenient explicit expressions for the steady-state distribution, without writing down any partial differential equations or performing any numerical integration. We call these tractable diffusion processes piecewise linear; the drift function is piecewise linear, while the diffusion coefficient is piecewise constant. The explicit expressions for steady-state distributions, in turn, yield explicit expressions for long-run average costs in optimization problems, which can be analyzed with the aid of symbolic mathematics packages. Since diffusion processes have continuous sample paths, approximation is required when they are used to model discrete-valued processes. We discuss strategies for performing this approximation, and we investigate when this approximation is good for the steady-state distribution of birth-and-death processes. We show that the diffusion approximation tends to be good when the difference between the birth and death rates is small compared to the death rates.

18.1 INTRODUCTION AND SUMMARY

In the natural sciences, diffusion processes have long been recognized as relatively simple stochastic processes that can help describe the first-order behavior of important phenomena. This simplicity is illustrated by the relatively quick way that the model is specified in terms of a drift function and a diffusion function (plus boundary behavior, which, here, we will take to be standard). However, the

©1982 by CRC Press, Inc.  463
analysis of diffusion processes can involve some formidable mathematics, which can reduce the appeal, and evidently has impeded applications to queueing problems. Our purpose, here, is to circumvent the formidable mathematics and focus solely on creating the model and obtaining the answer, which here is regarded as the steady-state distribution. From a theoretical standpoint, very little, here, is new. Our goal is to show that diffusion processes are easier to work with than often supposed.

For accessible introductory accounts of diffusion processes, see Glynn [11], Harrison [15], §§4 and §13.2 of Heyman and Sobel [17], Chapter 15 of Karlin and Taylor [20], and Chapter 7 of Revell [27]. For accessible advanced treatments, see Billingsley [4], Breiman [5], Ethier and Kurtz [7], Karatzas and Shreve [19], and Mandl [25].

A diffusion process is a continuous-time Markov process \(X(t) : t \geq 0\) with continuous sample paths. We will consider only real-valued, time-homogeneous diffusion processes. Such a diffusion process is characterized by its drift function or infinitesimal mean

\[
\mu(x) = \lim_{\varepsilon \to 0} \mathbb{E}[X(t + \varepsilon) - X(t) | X(t) = x],
\]

its infinitesimal variance

\[
\sigma^2(x) = \lim_{\varepsilon \to 0} \mathbb{E}[(X(t + \varepsilon) - X(t))^2 | X(t) = x],
\]

and its boundary behavior. We assume that the state space is the subinterval \((a_0, a_1)\), where \(-\infty < a_0 < a_1 < +\infty\). If the boundary points \(a_0\) and \(a_1\) are finite, then we assume that the boundaries are reflectors. It is easy to understand what reflecting means by thinking of what happens with an approximating simple random walk; from the boundary, the next step is back into the interior. If the boundary points are not finite, then we assume that they are inaccessible (cannot be reached in finite time). The boundary behavior can be subtle, and non-standard variations can be relevant for applications, e.g., see Harrison and Lenole [16], Kella and Whitt [22], and Kella and Takacs [21]. However, here we consider only the standard case.

We call the diffusion processes, that we consider, piecewise-linear diffusions, because we assume that the drift function \(\mu(x)\) is piecewise-linear and the diffusion function \(\sigma^2(x)\) is piecewise-constant in the state \(x\). These piecewise-linear diffusion processes are of interest both as models in their own right and as approximations. The piecewise-linear diffusions can serve as approximations for both non-diffusion processes (e.g., birth-and-death processes, see Section 18.3) and diffusion processes with more general piecewise-continuous drift and diffusion functions. In some of the literature on diffusion processes, it is assumed that the drift function and diffusion coefficient are continuous, e.g., see p. 119 of Karlin and Taylor [20], but this stronger assumption is actually not necessary, as can be seen from pp. 13, 25, 90 of Massey [25] and other references.

An example of a piecewise-linear diffusion process is the heavy-traffic diffusion approximation for the GI/M/c queue developed by Revell [27], Balachandran and Franta [12], and Hallin and Whitt [14]. This diffusion approximation plays an important role in approximations for the general GI/G/c queue in Whitt [33, 34, 38]. In this diffusion process, the drift is constant when all servers are busy and linear otherwise, while the variance is constant throughout. In the context of the GI/M/c example, our purpose is to show that the steady-state distribution can be immediately written down and understood. For this example, it will become
evident that the steady-state distribution of the diffusion process has a density that is a piece of an exponential density connected to a piece of a normal density.

Another example of a piecewise-linear diffusion process occurs in the diffusion approximation for large trunk groups in circuit-switched networks with trunk reservation; see Reiman [28,29]. These papers illustrate optimization applications, which we discuss in Section 18.7. All these examples involve queues with state-dependent arrival and service processes; for more examples of this kind, see Whitt [35] and references cited there. A nonqueuing example is the two-drift skew Brownian motion in the control problem of Renko, Shepp and Wittenstein [26]; see §6.5 of Karatzas and Shreve [19].

It should be clear that, when we use a diffusion approximation for a queuing process, we are assuming that we can disregard the detailed discrete behavior of the queuing process. The diffusion approximation tends to be appropriate when the jumps are relatively small compared to the magnitude of the process, which tends to occur under heavy loads. Formally, diffusion approximations can be justified by heavy-traffic limit theorems, in which we consider a sequence of models with an associated sequence of traffic intensities approaching the critical value for stability from below, e.g., see Balin and Whitt [12].

We now specify, in more detail, what we mean by piecewise linear. We assume that there are $k + 1$ real numbers $e_i$ such that $-\infty < e_0 < e_1 < \ldots < e_k < \infty$. Then, the state space is $(e_0, e_k)$ with $p(i; x) = a_0 x + b_0$ and $\sigma^2(x) = s_0^2 > 0$ on the interval $(e_{i-1}, e_i)$, $1 \leq i \leq k$. (Often the variance function can be regarded as constant overall, but we will consider the general case; motivation is given in Section 18.3.) As indicated above, if the boundary points $e_0$ and $e_k$ are finite, then, we assume that they are reflecting. Otherwise, we assume that they are inessential. Moreover, if $e_0 = -\infty$, then, we require that $a_1 > 0$ of ($a_0 = 0$ and $b_0 > 0$). Similarly, if $e_k = +\infty$, then, we require that $a_k < 0$ or ($a_k = 0$ and $b_k < 0$). From pp. 12, 26, 90 of Mandl [25], these conditions guarantee the existence of a proper steady-state limit (convergence in distribution).

The important point is that the steady-state limit has a density of the form

$$f(x) = p_i f_i(x), \quad e_{i-1} < x < e_i,$$  \hspace{1cm} (18.3)

where $\sum_{i=1}^{k} p_i = 1$, $\int f_i(x) dx = 1$, $f_i$ has a known relatively simple form and $p_i$ can be easily computed. Consequently, the steady-state mean, is

$$\mu = \int_{e_0}^{e_k} x f(x) dx = \sum_{i=1}^{k} e_i m_i,$$  \hspace{1cm} (18.4)

where $m_i$ is the mean of $f_i$, and similarly for higher moments. In particular, is Section 18.3, we show that

$$P_i = \frac{r_i}{\sum_{j=1}^{k} r_j}, \quad 1 \leq i \leq k,$$  \hspace{1cm} (18.5)

where $r_1 = 1$ and

$$r_i = \prod_{j=1}^{i-1} \frac{\sigma_j^2 \int_{e_{j-1}}^{e_j} f_j(x) dx}{\sigma_i^2 \int_{e_{i-1}}^{e_i} f_i(x) dx}, \quad 2 \leq i \leq k.$$  \hspace{1cm} (18.6)

Since the component densities $f_i$ are all continuous, the overall density $f$ is continuous if, and only if, $s_i^2 = s_j^2$ for all $i$. In all cases, the cumulative distribution func-
tion is continuous. Our experience indicates that, for most queueing applications, it is appropriate to have \( \sigma^2 \geq \rho \) and, thus, a continuous steady-state density.

For piecewise-linear diffusions with \( 0 < \sigma \leq \rho \) for all \( i \), the component densities \( f_i \) in (28.3) have a relatively simple form, so that it is easy to calculate the component means \( \mu_i \) (and second moments) and the probability weights \( p_i \) without performing any integrations. This makes the characterization attractive as an algorithm when \( k \) is large, as well as as insightful representation when \( k \) is small. In particular, if \( 0 < \sigma \leq \rho \) for all \( i \), then the component densities are all truncated and renormalized pieces of normal, exponential, and uniform densities. The relatively simple form for the steady-state distribution follows quite directly from the general theory, as we indicate in Section 18.4, but it does not seem to be well-known (among non-experts).

Conceptually, the characterization can be explained by the properties of truncated reversible Markov processes; see 3.6 of Kelly [23]. If the state space of a reversible Markov process is truncated (and given reflecting boundaries), then the truncated process is reversible with a steady-state distribution which is a truncated and renormalized version of the original steady-state distribution, i.e., the truncated steady-state distribution is the conditional steady-state distribution of the unrestricted process given the truncation subset. This property holds for multidimensional reversible Markov processes, but we restrict attention here to real-valued processes. For a multidimensional diffusion process application, see Feindick and Hernandez-Valencia [9]. This truncation property is also a natural approximation more generally, e.g., see Whitt [33].

For example, if a diffusion process on the real line behaves like an Ornstein-Uhlenbeck (OU) diffusion process over some subinterval of the state space, then its steady-state distribution restricted to that subinterval is a truncation and renormalization of the normal steady-state distribution of the full OU process with those parameters. Moreover, by exploiting basic properties of the normal distribution, it is possible to give explicit expressions for the moments of the conditional distribution restricted to this subinterval; see Proposition 18.3 below. These explicit expressions, in turn, help produce closed-form expressions for long-run average costs in optimization problems; see Section 18.7. This makes it possible to tackle the optimization problems with symbolic mathematics packages such as Maple V; see Char et al. [6].

Here is how the rest of the chapter is organized. In Section 18.2, we discuss diffusion approximations for birth-and-death processes and give some examples showing how piecewise-linear diffusions can naturally arise. In Section 18.3, we present the steady-state distribution of a piecewise-continuous diffusion, drawing on the basic theory in Karlin and Taylor [28] and Mandl [26]. In Section 18.4, we present four basic linear diffusion processes whose restrictions will form the pieces of the piecewise-linear diffusion process. In the cases with \( 0 < \sigma \leq \rho \), we exhibit the appropriate conditional distribution and its first two moments. In Section 18.5, we establish a stochastic comparison that can be used to show that piecewise-linear diffusions, which serve as approximations for a more general piecewise-continuous diffusion, actually are stochastic bounds. In Section 18.6, we investigate when the simple diffusion approximation for birth-and-death processes, introduced in Section 18.2, should be reasonable. In Section 18.7, we discuss optimization. Finally, we state our conclusions in Section 18.8.

In this chapter, we only consider steady-state distributions. However, it should be noted that diffusion processes can also help us understand transient
18.2 DIFFUSION APPROXIMATIONS

We often can obtain a diffusion process as an approximation of another process. In this section, we briefly discuss how.

18.2.1 Diffusion approximations of Birth-and-Death processes

We first discuss approximations of birth-and-death (BD) processes. As we indicate in Section 18.6 below, the steady-state distribution of a birth-and-death process is not difficult to calculate directly. However, in some cases, it may be desirable to have the closed-form formulas (18.3)-(18.6), especially when the number of places is small.

We begin by showing how a diffusion process can arise as a limit of a sequence of birth-and-death processes. To express the limiting behavior, let $[x]$ be the greatest integer less than or equal to $x$. For each positive integer $n$, let \( \{B_n(t) \mid t \geq 0\} \) be a birth-and-death process on the integers from \( \lceil \sqrt{n} \rceil \) to \( \lceil \sqrt{n} \rceil \) with state-dependent birth-and-death rates \( \beta_n(j) \) and \( \delta_n(j) \), respectively. Let the boundary behavior be the same as assumed for the diffusion processes. Let

\[
X_n(t) = \frac{B_n(t) - c_n}{\sqrt{n}}, \quad t \geq 0. \tag{18.7}
\]

In the context of (18.7), the drift and diffusion functions of \( X_n(t) \) are

\[
\mu_n(x) \equiv \lim_{\epsilon \downarrow 0} E X_n(t + \epsilon) - X_n(t) \mid X_n(t) = x = \frac{\beta_n(x + \epsilon \sqrt{n}) - \delta_n(x + \epsilon \sqrt{n})}{\sqrt{n}} \tag{18.8}
\]

and

\[
\sigma_n(x) \equiv \lim_{\epsilon \downarrow 0} E (X_n(t + \epsilon) - X_n(t))^2 \mid X_n(t) = x = \frac{\beta_n(x + \epsilon \sqrt{n}) + \delta_n(x + \epsilon \sqrt{n})}{\sqrt{n}} \tag{18.9}
\]

If \( n \to \infty, \) \( n \to \infty, \) \( \mu_n(x) \to \mu(x) \) and \( \sigma_n(x) \to \sigma^2(x) \) as \( n \to \infty, \) then \( X_n(t) \) can be said to converge to the diffusion process on \( (x, \infty) \) with drift function \( \mu(x) \) and diffusion function \( \sigma^2(x) \); see Stone [91] and Felsenstein [18]. This convergence is in a strong sense, including the finite-dimensional distributions of the stochastic processes and more, see Billingsley [4], but we will consider only the steady-state distributions.

Convergence of the steady-state distributions can be shown directly by a modification of the argument in Section 18.6 below.

Example 18.1. The M/M/1 queue. The number of customers in the system in the classical M/M/1 queue is a birth-and-death process with birth (arrival) rate \( \beta(j) = \beta_0 \) and death rate \( \delta(j) = \delta_0 \min(j, \infty) \), where \( \delta_0 \) is the individual service rate. For states in the interval \( (0, \infty) \), we have \( \delta(j) = \delta_0 \), while, for states in the interval \( (\infty, \infty) \), we have \( \delta(j) = \infty \). Consider a sequence of M/M/1 queueing models indexed by \( n \). In model \( n \), let the number of servers be \( x_n = n \), let the arrival rate be \( \beta_n(j) = n - \alpha \sqrt{n} \) for all \( j \), and let the individual service rate be \( 1, \)
so that the death rate is \( \lambda(j) = \min(j, n) \). Then it is natural to let \( c_0 = n \), so that \( l_0 = -n \) and \( u_0 = +\infty \). Then we have convergence to a diffusion process, as shown in Balin and Whitt [8].

Of course, in applications, we typically have only one birth-and-death process. Then, we can form the diffusion approximation by letting \( l_0 = l_n \), \( u_0 = u_n \), \( \mu(x) = \mu(x) \) and \( \sigma^2(x) = \sigma^2(x) \) where \( \mu(x) \) and \( \sigma^2(x) \) are defined by (18.6) and (18.7) for some given \( n \), which we take as \( n = 1 \). Setting \( n = 1 \) corresponds to simply matching the infinitesimal mean and variance. Based on Berger and Whitt [9], 8.5, we suggest refining the direct diffusion approximation by making the state space for the diffusion process \( l(-1/2, +1/2) \) instead of \( (0, n) \). This corresponds to the familiar refinement when a continuous (e.g., the normal) distribution is used to approximate an integer-valued probability distribution; see p. 185 of Feller [9].

Henceforth, here, we will concentrate on the direct approximation for the steady-state distribution of a birth-and-death process based on \( n = 1 \). We hasten to point out that a user should check whether the accuracy of the approximation is adequate for the intended application. We investigate when the crude direct approximation for the steady-state distribution is reasonable in Section 18.6.

Suppose that the birth-and-death parameters \( \beta \) and \( \delta \) are both linear; i.e., \( \beta(j) = \beta_0 + \beta_1 j \) and \( \delta(j) = \delta_0 + \delta_1 j \) for \( 1 \leq j \leq u \). Instead of (18.8) and (18.9), we can use the linear approximations

\[
\mu(x) = \beta_0 + \beta_1 x - \delta_0 - \delta_1 x
\]

(18.10)

and

\[
\sigma^2(x) = \delta_0 + \beta_1 + \beta_1 x + \delta_0 - x
\]

(18.11)

for \( l = l_0 \leq x \leq n + 1/2 \). Furthermore, assuming that the process will mostly be in the region of \( \sigma(x) \) in which \( \mu(x) = 0 \), we can further approximate the variance by

\[
\sigma^2(x) \approx \beta_0 + \beta_1 + \delta_0 + \delta_1
\]

(18.12)

provided that \( \mu(x) \approx 0 \) for some \( x \) with \( l = l_0 \leq x \leq n + 1/2 \). Otherwise, we let \( \sigma^2(x) \) be either \( \sigma^2(l) \) or \( \sigma^2(u) \), whichever is closer.

Finally, even when \( \beta \) and \( \delta \) are not linear, we may be able to produce (18.10) and (18.12) over subintervals by making a piecewise-linear approximation.

Example 18.1 (continued). Returning to the M/M/s queue, we apply (18.8) and (18.9) to obtain \( \mu(x) = \beta_0 - \gamma x \) and \( \sigma^2(x) = 2\beta_0 x + (1/2 + \gamma x) \), and \( \mu(x) = \beta_0 - \gamma x \) over \( (x - 1/2, \infty) \). To have constant variance overall, we argue that \( \sigma^2(x) \approx 0 \) for \( x = \infty \), so that \( \beta_0 = \gamma \); thus, we have the further approximation \( \sigma^2(x) \approx 2\beta_0 \) for \( x \in (0, \infty) \) as well as for \( x \in [0, 1] \). The relevant values of \( x \) are \( s + e/\sqrt{c} \) for some constant \( c \). For this example, the exact steady-state distribution of the birth-and-death process conditions a truncated Poisson distribution below \( s \) with a truncated geometric distribution above \( s \), while the diffusion approximation yields a truncated normal distribution below \( s \) and a truncated exponential distribution above \( s \); see Balin and Whitt [8].

These approximations often tend to be good, as is well-known.

Example 18.2. Secondary servers with a buffer. We now consider an example of a birth-and-death process with three linear regions. There is a service facility with one primary server plus a buffer of capacity \( c_1 \). There are \( c_2 \) secondary servers that accept overflows from the primary buffer. There is an additional buffer of capacity \( c_2 \) to hold arrivals when all servers are busy. The secondary system is costly, so that, whenever space opens up in the primary buffer, a customer in
service in the secondary system immediately leaves and enters the primary buffer. With this last feature, the number of customers in the system can be modeled as a birth-and-death process.

Let the arrival rate be constant, so that \( \lambda_j = \beta_0 \) for all \( j \). The service rate is linear in the three regions

\[
\delta(k) = \begin{cases} 
\eta_1, & 1 \leq k < c_1 + 1 \\
\eta_1 + (k - c_1 - 1)\eta_2, & c_1 + 1 \leq k < c_1 + c_2 + s + 1 \\
\eta_1 + \sigma_2p, & c_1 + c_2 + s + 1 \leq k \leq c_1 + c_2 + s + 1. 
\end{cases}
\]

(18.13)

The resulting direct diffusion approximation an drift function

\[
\mu(x) = \begin{cases} 
\beta_0 - \eta_1, & -1/2 \leq x < c_1 + 1/2 \\
\beta_0 - \eta_1 - (x - c_1 - 1)\eta_2, & c_1 + 1/2 \leq x < c_1 + c_2 + s + 3/2 \\
\beta_0 - \eta_1, & c_1 + c_2 + s + 3/2 \leq x < c_1 + c_2 + s + 3/2 
\end{cases}
\]

(18.14)

and diffusion function

\[
\sigma^2(x) = \begin{cases} 
\beta_0 + \eta_1, & -1/2 \leq x < c_1 + 1/2 \\
\beta_0 + \eta_1 + (x_0 - c_1 - 1)\eta_2, & c_1 + 1/2 \leq x < c_1 + c_2 + s + 3/2 \\
\beta_0 + \eta_1 + \sigma_2p, & c_1 + c_2 + s + 3/2 \leq x \leq c_1 + c_2 + s + 3/2 
\end{cases}
\]

(18.15)

provided that

\[
\mu(x_0) = \beta_0 - \eta_1 - (x_0 - c_1 - 1)\eta_2 = 0.
\]

(18.16)

for \( c_1 + 3/2 \leq x_0 < c_1 + c_2 + s + 3/2 \). If \( \mu(x) > 0 \) \((< 0)\) for all \( x \) in this region, then we can set \( \sigma^2(x) = \sigma^2(c_1 + s + 3/2)^{(2)} \) \((\sigma^2(x) = \sigma^2(c_1 + c_2 + 3/2))\).

Note that (18.15) and (18.16) lead to a piecewise-constant diffusion function. We can further simplify (18.15) by just letting \( \sigma^2(x) = \beta_0 \), assuming that \( \mu(x) = 0 \) over the entire range of relevant values.

### 18.2.2 Diffusion approximations for general integer-valued processes

Diffusion approximations are even more important when the stochastic process being approximated is not a birth-and-death process, because, then, there may be no alternative formula for the steady-state distribution. The crude direct approximation, above, easily generalizes; we just match the infinitesimal means and variances, as in (18.8) and (18.9). However, the infinitesimal means and the variances are often hard to determine. An alternative approach is to match the large-time behavior, as discussed in Whitt [32] and references cited there.

To match the large time behavior, let \( X_j(t) \) be a given integer-valued stochastic process and let \( X_j(t) \) be the time when \( X \) has spent \( t \) units of time in state \( j \). To formally define \( X_j(t) \), let \( T_j(t) \) be the time when \( X \) has spent \( t \) units of time in state \( j \), defined by setting

\[
T_j(t) = \int_0^t 1_{\{X(u) = j\}} du
\]

(18.17)

where \( 1_A \) is the indicator function of the set \( A \). Let \( \xi_j \) be the time of the \( j \)th jump
of X, and let \( N(t) \) be the number of jumps of X in \( [0, t] \). Then

\[
X_t(\ell) = \sum_{\ell=1}^{N(t)} (X(\ell) - J_{\ell-1}) I_{\{X(\ell - 1) > 0\}}, \quad t \geq 0. \tag{18.18}
\]

Typically, we can only approximately determine \( \{X_\ell(t) : t \geq 0\} \), but even an estimate can serve as the basis for the diffusion approximation.

We assume that \( \{X_\ell(t) : t \geq 0\} \) obeys a central limit theorem, i.e.,

\[
\frac{X_m(t) - \lambda t}{\sqrt{\lambda \sigma^2(t)}} \Rightarrow \mathcal{N}(0, 1) \quad \text{as } t \to \infty, \tag{18.19}
\]

where \( \mathcal{N}(0, 1) \) is a standard (zero mean, unit variance) normal random variable and \( \Rightarrow \) denotes convergence in distribution. We then, create the distribution approximation by first setting

\[
\mu(j) = \lambda J_j \quad \text{and} \quad \sigma^2(j) = \lambda \sigma_j^2 \tag{18.20}
\]

and then fitting continuous functions to \( \mu(j) \) and \( \sigma^2(j) \). It is easy to see that this procedure coincides with (18.8) and (18.9) with \( \alpha = 1 \) when \( X \) is a birth-and-death process, but it also applies more generally.

### 18.2.3 Birth-and-death approximations

Since birth-and-death processes are also relatively easy to work with, we could consider constructing approximating birth-and-death processes instead of approximating diffusion processes. This might be convenient for looking at the time-dependent behavior, e.g., for doing simulation or optimization via Markov programs in the spirit of Kushner and Dupuis [24]. However, it is not as easy to approximate by a birth-and-death process as it is by a diffusion process.

Starting from a diffusion process, we can obtain an approximating birth-and-death process by solving (18.8) and (18.9) for the birth-and-death rate functions \( \beta \) and \( \delta \). In particular, we get

\[
\beta(j) = \frac{\sigma^2(j) + \mu(j)}{2} \quad \text{and} \quad \delta(j) = \frac{\sigma^2(j) - \mu(j)}{2}. \tag{18.21}
\]

Obviously, this birth-and-death construction works only when \( \sigma^2(j) \geq \mu(j) \) for all \( j \). When \( \sigma^2(j) \) is significantly less than \( \mu(j) \), we should not anticipate that a birth-and-death approximation will be good.

We also note that piecewise-linear birth-and-death processes can be considered. The geometric, Poisson, and discrete uniform distributions play the role of the exponential, normal, and continuous uniform distributions below. The truncation property holds because the birth-and-death process is also a reversible Markov process.

### 18.3 PIECEWISE-CONTINUOUS DIFFUSIONS

We now exhibit the steady-state distribution for a (time-homogeneous) diffusion with piecewise-continuous drift and diffusion functions \( \mu(x) \) and \( \sigma^2(x) \), with \( \sigma^2(x) > 0 \). As before, we use the \( k + 1 \) points \( x_i \) and assume that the drift and diffusion coefficients are continuous on \( (x_{i-1}, x_i) \) with limits from the left and
right at each $x_i$ for each $i$; see pp. 13, 26 and 90 of Mandl [35]. We also assume that the boundary points $s_0$ and $s_k$ are reflecting, if finite, and inscrutable, if infinite. We assume there is a proper time-dependent distribution which converges to a proper steady-state distribution with density $f(x)$. (For the piecewise-linear case, this follows from the extra structure.) The general theory implies that

$$f(x) = \frac{m(x)}{M(s_k)}$$

where

$$m(x) = \frac{2}{\sigma^2(x)}$$

is the speed density,

$$\sigma(x) = \exp\left\{ \int_{s_0}^{x} \frac{2\sigma(y)}{\sigma^2(y)} dy \right\}$$

is the scale density with $\theta$ arbitrary satisfying $s_0 < \theta < s_k$, and

$$M(x) = \int_{s_0}^{x} m(y) dy$$

provided that all integrals are finite, see pp. 13, 25, 90 of Mandl [35] and §15.3 and 15.6 of Karlin and Taylor [26].

From (18.22)-(18.25), we see that the density $f(x)$ can easily be calculated by numerical integration. Our object is to obtain more convenient explicit expressions. From (18.24) and (18.25), we see that $\sigma(x)$ and $M(x)$ are continuous on $(s_0, s_k)$, so that $m$ and $f$ are continuous everywhere is the interval $(s_0, s_k)$ except perhaps at the points $x_i$, $1 \leq i \leq k - 1$, where $\sigma^2(x)$ is discontinuous. Indeed, since $\sigma^2(x)$ has positive limits from the left and the right at $x_i$ for each $i$, $1 \leq i \leq k - 1$, we will the density $f(x)$ and we can relate the right and left limits. In particular,

$$f(x_i^+) = \frac{\sigma^2(x_i^-)}{\sigma^2(x_i^+)} f(x_i^-).$$

From (18.26) and (18.3), we easily obtain the formula for the probability weights in (18.5).

From (18.22)-(18.25), we also directly deduce that the conditional density, conditioning on a subinterval is $f(x)$ for $x$ in this subinterval. Moreover, this conditional density is the steady-state density of the diffusion process obtained by restricting the original diffusion process to this subinterval, using reflecting boundaries at all finite boundary points.

1.6.4 FOUR BASIC LINEAR DIFFUSION PROCESSES

We construct the component densities $f_i$ in (18.3) from the steady-state densities of four basic diffusion processes

18.4.1 The Ornstein-Uhlenbeck diffusion process

if
\[ \mu(x) = -a(x-m) \quad \text{and} \quad \sigma^2(x) = \sigma^2 > 0 \] (18.27)

for \( a > 0 \) and \(-\infty < x < \infty\), then we have the Ornstein-Uhlenbeck (OU) process, for which the steady-state limit is normally distributed with mean \( m \) and variance \( \sigma^2/2a \).

Let \( N(m,\sigma^2) \) denote a normally distributed random variable with mean \( m \) and variance \( \sigma^2 \). Let \( \Phi \) be the cumulative distribution function (cdf) and \( \phi \) the density of \( N(0,1) \). If \( X \) is the steady-state distribution of the OU process in (18.27) restricted to the interval \((x_{i-1}, x_i)\), then \( X \) has the distribution of \( N(m,\sigma^2/2a) \) conditioned to be in the interval \((x_{i-1}, x_i)\), i.e., \( X \) has the density

\[ f(x) = \frac{b^{-1} \Phi \left( \frac{x-m}{b} \right) - \Phi \left( \frac{x_{i-1}-m}{b} \right)}{\Phi \left( \frac{x_i-m}{b} \right) - \Phi \left( \frac{x_{i-1}-m}{b} \right)} \quad x_{i-1} < x < x_i \] (18.28)

where \( b^2 = \sigma^2/2a \).

Of course, the cdf \( \Phi \) appearing in (18.28) involves an integral, but it can be calculated approximately without integrating using numerical approximations; see §26.3 of Abramowitz and Stegun [1].

Note that we can easily infer the shape of \( f \) from (18.28). For example, \( f \) is unimodal; the mode is in the interior of \((x_{i-1}, x_i)\), and, thus, at \( m \), if, and only if, \( x_{i-1} < m < x_i \). In general, \( f(x) \) increases as \( x \) moves toward \( m \).

The following proposition gives the first two moments of \( X \).

Proposition 18.3. If \(-\infty < x_{i-1} < x_i < \infty\), then

\[ \mathbb{E}[N(m,b^2) \mid x_{i-1} \leq N(m,b^2) \leq x_i] = m + b \left[ \Phi \left( \frac{x_{i-1}-m}{b} \right) - \Phi \left( \frac{x_i-m}{b} \right) \right] \] (18.29)

and

\[ \mathbb{E}[N(m,b^2)^2 \mid x_{i-1} \leq N(m,b^2) \leq x_i] = m^2 + 2mb \left[ \Phi \left( \frac{x_{i-1}-m}{b} \right) - \Phi \left( \frac{x_i-m}{b} \right) \right] + b^2 \]

\[ + b^2 \left[ \Phi \left( \frac{x_{i-1}-m}{b} \right) - \Phi \left( \frac{x_{i-1}-2m}{b} \right) \right] \]

\[ - b^2 \left[ \Phi \left( \frac{x_{i-1}-m}{b} \right) - \Phi \left( \frac{x_{i-2}-m}{b} \right) \right] \] (18.30)

Proof. First note that \( \phi(x) = -\phi(-x) \) for all \( x \), so that

\[ \mathbb{E}[N(0,1) \mid x_{i-1} \leq N(0,1) \leq x_i] = \frac{\Phi(x_{i-1}) - \Phi(x_i)}{\Phi(x_{i-1}) - \Phi(x_{i-2})} \]

Consequently,

\[ \mathbb{E}[N(m,b^2) \mid x_{i-1} \leq N(m,b^2) \leq x_i] = m + \mathbb{E} \left[ \frac{N(m,b^2)-m}{b} \mid x_{i-1} \leq N(m,b^2) \leq x_i \right] \]

\[ = m + \mathbb{E} \left[ \frac{N(0,1)-0}{b} \mid x_{i-1} \leq N(0,1) \leq x_i \right] \leq N(0,1) \leq x_i \]
Next note that $x^2\varphi(x) = \varphi(x) + \varphi''(x)$, so that
\[
E[N(0,1)^2 | \xi_{i-1} \leq N(0,1) \leq \xi_i] = 1 + \frac{\varphi(\xi_{i-1}) - \varphi(\xi_i)}{\varphi''(x)}
\]
Consequently,
\[
E[N(0,1)^2 | \xi_{i-1} \leq N(0,1) \leq \xi_i] = 1 + \frac{\varphi(\xi_{i-1}) - \varphi(\xi_i)}{\varphi''(x)}
\]
\[
+ 2m\varphi(N(0,1)) | \xi_{i-1} \leq N(0,1) \leq \xi_i
\]
\[
+ \frac{\varphi(\xi_{i-1}) - \varphi(\xi_i)}{\varphi''(x)} N(0,1) \leq \xi_i
\]

### 18.4.2 Reflected Brownian motion with zero drift

If
\[
\mu(x) = 0 \quad \text{and} \quad \sigma^2(x) = \sigma^2 > 0
\]
on $(-\infty, \xi_{i-1}, \xi_i)$ for $-\infty \leq \xi_{i-1} < \xi_i < +\infty$, then we have the reflected Brownian motion (RBM) process with zero drift, for which the steady-state limit $X$ is uniformly distributed on $(\xi_{i-1}, \xi_i)$ with mean $(\xi_{i-1} + \xi_i)/2$ and second moment $(\xi_{i-1}^2 - \xi_i^2)/2\sigma^2$. The conditional distribution on $x$ is uniform with the new endpoints playing the role of $\xi_{i-1}$ and $\xi_i$.

### 18.4.3 Reflected Brownian motion with drift

If
\[
\mu(x) = -\alpha \quad \text{and} \quad \sigma^2(x) = \sigma^2 > 0
\]
for $0 > \alpha$ on $(\xi_{i-1}, \xi_i)$, then we have RBM with negative drift, for which the steady-state limit is distributed as $x \pm \alpha$ an exponential with mean $\sigma^2/2\alpha$. This case also covers RBM with positive drift $\alpha$ on $(-\infty, -\alpha)$, say, $(\alpha(X); t \geq 0)$, because $(-\alpha(X); t \geq 0)$ is then the RBM with negative drift above. Hence, if $f$ and $\alpha$ are the steady-state densities with negative and positive drift, respectively, then $g(-x - \alpha) = f(x + \alpha)$ for $x \geq 0$. Hence, it suffices to focus only on the negative drift case.

It is well-known and easy to see that the conditional distribution of $x$ plus an exponential, given that it is contained in the interval $(\xi_{i-1}, \xi_i)$, where $\xi_{i-1} < x$, is the same as an exponential on $(\xi_{i-1}, \xi_i)$; i.e., the conditional density is
\[
f(x) = \frac{\lambda e^{-\lambda(x - \xi_{i-1})}}{1 - e^{-\lambda(x - \xi_{i-1})}} \quad \xi_{i-1} < x < \xi_i
\]
where $\lambda^{-1}$ is the mean of the exponential random variable, here $\lambda^{-1} = \sigma^2/2\alpha$.

Let $X$ be a random variable with the density $f$ in (18.33). Then elementary calculations yield
\[
E[X] = \xi_{i-1} + \lambda^{-1} \left[ 1 - e^{-\lambda(x - \xi_{i-1})} \right]
\]
\[
E[X^2] = \xi_{i-1}^2 + \lambda^{-1} \left[ 1 - e^{-\lambda(x - \xi_{i-1})} \right] \left( 1 + \lambda(x - \xi_{i-1}) \right)
\]
\[ + \lambda^{-1} \left[ \frac{1 - e^{-\lambda(a_x - a_{s-1})}}{1 - e^{-\lambda(a_x - a_{s-1})}} \right] \left[ 1 + \frac{\lambda^2(a_x - a_{s-1})^2}{2} \right] \]

where \( \lambda^{-1} = \sigma^2/2a \).

18.4.4 Positive linear drift

A relatively difficult case occurs if

\[ \mu(x) = a(x - m) \quad \text{and} \quad \sigma^2(x) = \sigma^2 > 0 \] (18.36)

for \( a > 0 \) and \( a_{s-1} < x < a_s \). Then, there is positive linear drift away from \( m \). By partitioning the interval into two subintervals and performing a change of variables, it suffices to consider the case

\[ \mu(x) = ax \quad \text{and} \quad \sigma^2(x) = \sigma^2 > 0 \] (18.37)

on \((0,s)\). However, even (18.37) is difficult. Indeed, no nice explicit form is available for (18.37). In particular, from (18.22)-(18.25), we see that the steady-state density (18.37), is of the form

\[ f(x) = Ke^{ax}/\sigma, \quad 0 \leq x \leq s, \] (18.38)

and the mean is

\[ E[X] = \frac{Ke^{as}/\sigma - 1}{2a} \] (18.39)

for a constant \( K \) such that \( \int_0^s f(x)dx = 1 \). Except for the constant \( K \), the forms of (18.38) and (18.39) are quite simple and thus easily understood. However, \( K \) does not have a simple expression. The constant \( K \) can be found from Dawson’s integral \( D(y) = e^{-y^2/2} \int_0^y e^{x^2} dx \), whose values appear in Table 7.5 of Abramowitz and Stegun [1]. The maximum value is \( D(y) = 0.541 \) occurring at \( y = 0.924 \); see 7.1.17 of Abramowitz and Stegun.

Since the constant \( K \) in (18.39) is relatively intractable, if this case is present, then we would resort either to direct numerical integration in the setting of Section 18.3 or approximation of the drift coefficient in (18.36) by piecewise-constant drift coefficients, as in Section 18.4.3 and Section 18.6.3, over several sub-intervals.

Example 18.4. Insurance fund. We now give a (punctuating) example with a positive state-dependent drift. As in Harrison [14], consider an insurance firm with an asset process that is a diffusion with state-dependent drift \( \mu(x) = ax \) for positive \( x \) where \( a > 0 \) and constant variance function, but let the process have a reflecting barrier at zero instead of the absorbing barrier. Moreover, combine this with De Finetti’s model of an insurance fund as discussed on pages 146-147 of Gerber [10], in which all proceeds above some level \( b \) are paid out as dividends. Then, the asset process is a linear diffusion on \([0,b]\) with drift function \( \mu(x) = ax \), where \( a > 0 \).

18.5 STOCHASTIC COMPARISONS

Since we may want to approximate a general piecewise-continuous diffusion by a
piecewise-linear diffusion, it is useful to have results providing insight into the quality of the approximation.

From Section 18.3, we easily obtain sufficient conditions for a stochastic comparison. We say that density $f_2$ is less than or equal to another $f_1$ on the same interval $(a, b)$ in the sense of stochastic ratio ordering, and we write $f_1 \leq_{s} f_2$ if $f_2(x)/f_1(x)$ is nonincreasing in $x$. A likelihood ratio ordering implies that the distribution determined by $f_1$ is stochastically less than or equal to the distribution determined by $f_2$, see note [30].

Proposition 18.5. Consider two piecewise-linear diffusions on a common interval $(a, b)$ satisfying (18.22)-(18.25). If $\pi_x(\tau)/\pi_y(\tau)$ is nondecreasing in $x$ and $\mu_2(x)/\sigma_2^2(x) \geq \mu_1(x)/\sigma_1^2(x)$ for all $x$, then $f_1 \leq_{s} f_2$.

Proof. Note that $f_2(x)/f_1(x)$ is nondecreasing if, and only if, $\sigma^2(x)\mu_2(x)/\sigma_1^2(x)\mu_1(x)$ is nondecreasing, by (18.22) and (18.23). Next, by (18.24), $s_1(x)/s_2(x)$ is nondecreasing if, and only if, $\mu_2(x)/\sigma_2^2(x) \geq \mu_1(x)/\sigma_1^2(x)$ for all $x$.

Note that the condition in Proposition 18.5 is satisfied if $\sigma^2(x) = \sigma_2^2(x)$ and $\mu_2(x) \leq \mu_1(x)$ for all $x$.

From (18.23)-(18.25), we can therefore establish continuity results showing that $f_{s}(x) = f(x)$ for each $x$ if $\rho_{x}(x) = \rho_{2}(x)$ and $q_{s}(x) = q_{2}(x)$ for each $x$, plus extra regularity conditions, for a sequence of piecewise-linear diffusions.

18.6 ON THE QUALITY OF DIFFUSION APPROXIMATIONS FOR BIRTH-AND-DEATH PROCESSES

We, now, investigate when the direct diffusion approximation for birth-and-death processes with $n = 1$ in (18.8) and (18.9) is reasonable for the stationary distribution for the birth-and-death process. For simplicity, we assume that $t > -\infty$. Recall that the steady-state probability mass function for a birth-and-death process is

$$\tau_j = \rho_j \sum_{i=1}^{j} \rho_i \quad 1 \leq j \leq n,$$

(18.40)

where $\rho_j = 1$ and

$$\rho_j = \prod_{i=1}^{j} \left(1 - \frac{\beta_i}{\gamma_i} \right) = \frac{\beta_j}{\gamma_j} \exp \sum_{i=1}^{j-1} \log \left(1 - \frac{\beta_i}{\gamma_i} \right), \quad 1 \leq j \leq n.$$

(18.41)

To relate (18.41) to the steady-state distribution of the diffusion, we exploit the properties of the logarithm, i.e., $\log(1 + x) = - \frac{x^2}{2} + \frac{x^3}{3} - \ldots$.

From (18.41) and (18.42), we obtain a condition for the diffusion approximation to be good. The condition is that $(\beta_i - \gamma_i)/\gamma_i$ is suitably small for the $i$ of interest. Assuming this is the case, we have

$$\rho_j = \gamma_j \prod_{i=1}^{j-1} \frac{\beta_i - \gamma_i}{\gamma_i} + \gamma_j \left(\frac{\beta_j - \gamma_j}{\gamma_j} + \cdots \right)^{j-1}.$$

(18.43)

From (18.8) and (18.9) with $n = 1$, $\beta_i = \sigma^2(i)/\sigma(i)^2$, $\gamma_i = \sigma^2(i)/\sigma(i)^2$, $\gamma_i = u(i)/2$ and

$$\rho_j = \frac{2\rho(i)}{\sigma(i)^2} \prod_{i=1}^{j-1} \frac{2\rho(i)}{\sigma(i)^2}.$$

(18.44)

If, in addition, $2\rho(i)/\sigma^2(i)$ is suitably smooth, e.g., linear, then
\[ \rho_j = \frac{2\gamma \sigma_j^2}{\sigma_j^2} \int_{j-1/2}^{j+1/2} \frac{2\mu(y)}{\sigma^2(y)} \, dy \]  
\tag{18.45}

and indeed, by (18.22), (18.23), (18.24), and (18.45),

\[ \tau_j \approx \int_{j-1/2}^{j+1/2} f(y) \, dy = f(j), \quad 1 \leq j \leq n, \]  
\tag{18.46}

where \( f \) is the diffusion process density in (18.22). Formula (18.46) shows that the steady-state birth-and-death probability mass function values \( \tau_j \) are reasonably approximated by the steady-state diffusion density \( f(j) \).

18.7 OPTIMIZATION

It can be rather straightforward to handle costs in a piecewise-linear diffusion process. Suppose a cost is charged to the system at rate \( g(x) \) per unit time when \( x \in [r_i, r_{i+1}) \). Then standard renewal-reward theory tells us that the expected average cost per unit time is

\[ \sum_{i=1}^{k} \rho_i \int_{r_{i-1}}^{r_i} g(x) f_*(x) \, dx. \]  
\tag{18.47}

We discuss one example of optimization below; see Bensel, Shepp and Witten (1974). It is straightforward to see that the optimal solution is given in (18.14) and (18.15). By the results of Sections 18.3 and 18.4, we find that in regions 1 and 3, the stationary distribution is truncated exponential, and in region 2 it is truncated normal. To simplify notation, we will let \( \beta_0 = \beta_1 = -\beta \leq 0 \) and \( \beta_0 + \beta_1 = \delta \). We also let \( (\beta_0 - \beta_1)/\sigma_2 = -\sigma \leq 0 \) and \( \sqrt{\beta_0/\beta_2} = \gamma \). Then, from

\[ f_1(x) = \frac{\lambda e^{-\lambda x} - \lambda e^{-\lambda(x + 1/2)}}{1 - e^{-\lambda(x + 1/2)}}, \]  
\tag{18.48}

\[ f_2(x) = C(x) \left( e^{-(x - m)\gamma} \right), \]  
\tag{18.49}

\[ f_3(x) = \frac{\lambda e^{-\lambda x} - \lambda e^{-\lambda(x + 1 + \sigma/\sqrt{\beta_0})}}{1 - e^{-\lambda(x + 1 + \sigma/\sqrt{\beta_0})}}, \]  
\tag{18.50}

where

\[ \lambda_i = \frac{\delta}{\beta_i} \frac{\gamma}{\sqrt{\beta_0}} \left( \frac{1}{2} + \frac{\sigma}{\sqrt{\beta_0}} \right)^{-1/2} \]  
\tag{18.51}

(18.51) follows from Section 18.4.1 that, for the normal part, we have the mean \( m = c_1 + 1 - \alpha \).

From (18.5) and (18.6), we also get \( r_1 = 1 \).

\[ r_2 = \frac{4 \lambda e^{-\lambda(x + 1/2)}}{(1 - e^{-\lambda(x + 1/2)})(\beta_0 C(x) \gamma((\alpha + 1/2)/\gamma) \beta_2 \gamma)} \]  
\tag{18.52}
and

$$r_3 = r_2 \left( \frac{1 - e^{-\lambda_3 t}}{\lambda_3 t} \right) \delta \left( \alpha + \beta + 1/2 \right) \gamma \left( \delta + \gamma \right) \delta \left( \alpha + \beta + 1/2 \right) \gamma \left( \delta + \gamma \right)$$  \hspace{1cm} (18.53)

Now we consider optimization problems. Even if we restrict attention to choosing the parameters $c_1$ and $c_2$ and $c_3$, there are quite a few possibilities. For example, the secondary servers could be a given, as would be the number of buffer spaces, $c_1 + c_2$. In this case, the decision problem would be how to split the buffers and where to place the secondary servers (if we restrict ourselves to using them as dedicated group). In extreme cases, we might want to place all of the buffer spaces in between the single server and secondary servers (if e.g. $c_1 < c_2$), or, in the other extreme (e.g. if $c_1 < \min(c_2, c_3)$), we may want to place all the servers together at the head of the system, thus effectively working as a partially ranked $M/M/1/c_1/c_2$ system with a strange cost structure. (In both of these cases, there would only be 2 regions.) We will call this Problem I.

Alternatively, the buffer spaces as well as their positions might be fixed externally, and the decision variable might simply be how many excess servers, $s$, to hire within a given budget constraint. We will call this Problem II.

In both cases, since processing occurs only in the regions 1 and 3, costs should be quadratic in those 2 regions, and linear in the region where service is in parallel. i.e., we will take $g_i(x) = \lambda_i(x - c_i - s_i)^2$, for $i = 1, 3$, and $g_2(x) = \lambda_2 (x - c_2)\gamma (x - (c_1 + c_2 + 1/2))$. Let $E[(c_1, s, c_2)]$ denote the cost function for the system. Then we have

$$E[(c_1, s, c_2)] = p_1 h_1 E(X_1 - s_1)^2 + p_2 h_2 E(X_2 - s_2) + p_3 h_3 E(X_3 - s_3)^2$$.

(18.54)

where $X_i$ has density $f_i$. These values are then easily obtained from (18.39) and (18.39), yielding

$$E(X_1 - s_1)^2 = \frac{1}{4} \left( 1 - e^{-\lambda_1 (c_1 + s_1 + 1/2)} \right) \lambda_1 (1 - e^{-\lambda_1 (c_1 + s_1 + 1/2)})$$

$$+ \frac{1}{4} \left( 1 - e^{-\lambda_1 (c_1 + s_1 + 1/2)} \right) \lambda_1 (1 - e^{-\lambda_1 (c_1 + s_1 + 1/2)})$$

(18.55)

$$E(X_2 - s_2) = c_2 + 1 + \frac{s_2^2}{2 c_2 (1 + \alpha/2) - s_2 (1 + \alpha/2)}$$

(18.56)

$$E(X_3 - s_3)^2 = (c_3 + 1 + s + 1/2)^2 + \frac{2 (c_3 + 1 + s + 1/2)^2}{\lambda_2} \left( 1 - e^{-\lambda_2 (c_3 + 1 + s + 1/2)} \right)$$

$$+ \frac{1 - e^{-\lambda_2 (c_3 + 1 + s + 1/2)}}{\lambda_2^2}$$

(18.57)

It should, of course, be recalled that $p_1 = p_2(c_1, s)$, $p_3 = p_3(c_1, s, c_2) h_3 = \lambda_3 (s)$.

Standard numerical optimization techniques can, now, be used to optimize the
system. For example, for Problem I, suppose that \( c_1 + v_1 = K \); then, let \( c_1 = c \) and \( c_2 = K - c \) in (18.34)-(18.37), and just optimize \( \mathbb{E}[B(t, X, K - c)] \) with respect to \( c \). The two extreme cases referred to above correspond, respectively, to the cases \( c = 0 \), \( c = K \). For Problem II, we would try to maximize \( z \) subject to \( \mathbb{E}[R(z, t, 0, K - c)] \leq I \), where \( I \) is our budget per unit time.

For example, we applied the symbolic mathematical package, Maple V, to differentiate \( \mathbb{E}[B(t, z, K - c)] \) with respect to \( c \) in order to find the optimal solution for Problem I; see Chat et al. [6]. Using piecewise-linear diffusion processes together with symbolic mathematics packages seems like a promising approach.

18.8 CONCLUSIONS AND OPEN PROBLEMS

In Sections 18.1, 18.2, and 18.4 we showed that the steady-state distribution of a one-dimensional piecewise-linear diffusion can be expressed conveniently in closed form, in a way that is insightful. It remains to obtain corresponding results for multidimensional diffusions.

In Sections 18.2 and 18.6, we discussed diffusion approximations for birth-and-death processes and other integer-valued processes. It remains to further evaluate the quality of these approximations.

In Sections 18.3 and 18.5, we discussed piecewise-linear diffusion approximations for more general diffusion processes with piecewise-continuous drift and diffusion functions. In Section 18.7, we showed how the piecewise-linear diffusion processes can be used effectively for optimization, especially when combined with a symbolic mathematics package such as Maple V. It remains to exploit the use of symbolic mathematics packages further. Moreover, it remains to develop effective algorithmic methods for solving and optimizing more complicated multidimensional diffusion processes; see Kushner and Dupuis [21] for significant progress in this direction.

Overall, we have tried to support the idea that one-dimensional diffusion processes can be useful for queueing and other applied problems.

ACKNOWLEDGEMENT

We thank Jerzy Dshalalow for helpful comments on the presentation.
