1 Introduction

Glasses are widely used in optical, electronic, and biomedical applications because of their excellent mechanical, thermal, and optical properties. For applications such as microfluidics, lab-on-a-chip, and flat panel displays, there is a need to join glasses. Proper use of optical and laser processing parameters generated structural rearrangement of the material through a thermal accumulation mechanism, which could be potentially used for the transmission welding process. The morphology of generated features was studied using differential interference contrast optical microscopy. In addition, the predictive capability of the morphology is developed via a finite element analysis. The change in mechanical properties was studied through employment of spatially resolved nanoindentation. The specimen was sectioned and nanoindents were applied at the cross section to examine mechanical responses of the laser-modified region. Fracture toughness measurements are carried out to investigate the effects of the laser treatment on strength of the glass. [DOI: 10.1115/1.4002062]

Femtosecond laser pulses were focused in the interior of a single fused silica piece. Proper use of optical and laser processing parameters generated structural rearrangement of the material through a thermal accumulation mechanism, which could be potentially used for the transmission welding process. The morphology of generated features was studied using differential interference contrast optical microscopy. In addition, the predictive capability of the morphology is developed via a finite element analysis. The change in mechanical properties was studied through employment of spatially resolved nanoindentation. The specimen was sectioned and nanoindents were applied at the cross section to examine mechanical responses of the laser-modified region. Fracture toughness measurements are carried out to investigate the effects of the laser treatment on strength of the glass. [DOI: 10.1115/1.4002062]
understanding of the change in mechanical properties such as modulus, hardness, ductility, and fracture toughness upon femtosecond laser irradiation of bulk transparent materials. The effects of laser processing parameters such as pulse energy and scanning speed on those mechanical properties are also reported.

2 Background

2.1 FS Laser Interaction and Feature Formation Mechanisms in the Interior of Glasses. When femtosecond laser pulses are focused in the interior of a transparent material, the laser intensity within the focal volume becomes extremely high resulting in nonlinear absorption. Due to the high intensity (>10^13 W/cm^2), free electrons are initially produced by multiphoton ionization. These electrons serve as seeds for subsequent avalanche ionization, through which a substantial number of free electrons will be produced. The probability of multiphoton ionization per atom per second, \( w_{\text{mp}} \), and that of avalanche ionization per unit time \( w_{\text{av}} \), are written as [15]

\[
w_{\text{mp}} \approx n_0 \left( \frac{E_0}{2E_L} \right)^{n_{\text{ph}}} \\
w_{\text{av}} \approx n_0 \left( \frac{2\omega_0 v_{\text{eff}}}{\omega_0 + v_{\text{eff}}} \right)
\]

where \( \omega \) is the laser frequency, \( v_{\text{eff}} \) is the electron-phonon collision frequency, \( n_{\text{ph}} \) is the number of photons necessary for the electron to be transferred from the valence to the conduction band, \( E_L \) is the ionization energy, and \( e_{\text{qs}} \) is the electron quiver energy in the laser field. \( e_{\text{qs}} \) has units of eV and is expressed in a scaling form [15], \( e_{\text{qs}} \approx 9.3(1 + \alpha^2)D_x^2/10^{14} \), where \( \alpha \) is the coefficient for beam polarization, \( f \) is the laser intensity in units of W/cm^2, and \( \lambda \) is the laser wavelength in units of \( \mu \)m. The density of free electrons, \( n_e \), from the two major mechanisms, multiphoton and avalanche ionization, is [15]

\[
n_e(I, \lambda, t) = \left( n_0 + \frac{w_{\text{mp}}}{w_{\text{av}}} \right) \left[ 1 - e^{-w_{\text{av}}t} \right] \times e^{w_{\text{av}}t}
\]

where \( n_0 \) is the density of initial seed electrons, \( n_e \) is the density of neutral atoms, and \( t \) is time. When the free electron density reaches the critical value, \( n_e \), the ionization threshold is achieved, and plasma is created in the material. This critical free electron density is described as [16]

\[
n_e = \frac{\pi m_e c^2}{e^2 \lambda^2} = \frac{m_e \omega_0^2}{4 \pi e^2}
\]

where \( m_e \) is the electron mass, \( c \) is the speed of light, \( e \) is the electron charge, and \( \lambda \) is the laser wavelength. The free electron density is saturated in a few femtoseconds at the beginning of the laser pulse. During the remaining part of the pulse, plasma strongly absorbs the laser pulse energy, which creates a region of high energy density. Subsequently after the end of laser pulse, the transfer of the energy from the hot plasma to the lattice results in structural changes in the bulk transparent material [16].

Depending on the optical and laser processing parameters, the bulk transparent material can be modified through the microexplosions or thermal accumulation mechanisms [17]. For the micro-explosion mechanism when a single laser pulse is deposited into the target material, high laser intensity created by either tight focusing of low energy pulse or loose focusing of high energy pulse cause shock wave generation. The shock wave carries matter and energy away from the focal volume, compressing the surrounding material while a rarefaction wave behind the shock front propagates into the opposite direction, creating a rarified central region or void [18]. As a result, a void surrounded by densified shell is generated. The thermal accumulation mechanism occurs, when multiple pulses either with low energy and high repetition rate or with high energy and low repetition rate are irradiated at same location or at low scanning speed. Heat accumulates inside the focal volume causing the localized melting, which is followed by heat conduction into the surrounding material. Due to rapid resolidification, the melted region subsequently solidifies into a higher density phase [19]. In the latter mechanism, the feature size is determined by a combination of pulse energy and repetition rate, the stage translation speed, and the NA of the objective lens.

2.2 Characterization of Mechanical Properties by Nanoindentation. Nanoindentation or depth-sensing indentation testing is a modern technique, which can be used to characterize the mechanical properties of materials at small length scales. An analysis of a load-displacement curve gives hardness and the elastic modulus of the indented material, which are expressed as [19]

\[
H_I = \frac{P}{A} = \frac{P}{\pi r_p^2 \tan^2 \alpha} \quad \text{and} \quad E_I = \frac{1}{2} \sqrt{\pi dP/\Delta z}
\]

where \( H_I \) is the indentation hardness, \( E_I \) is the indentation modulus representing the combined modulus of the indenter tip and the specimen, \( P \) is the indenter maximum load, \( z_p \) is the penetration depth, \( dP/\Delta z \) is the slope of the elastic unloading curve, and \( \alpha \) is the semi-angle for an equivalent conical indenter.

Lawn et al. [20] studied the deformation properties of materials using indentation tests. Their primary interest is in the brittle materials especially glasses. Using the condition for compatibility of the two half-cycles at the maximum load, the elastic recovery is

\[
\left( \frac{z_p}{z_m} \right)^2 = 1 - \frac{H}{E}
\]

where \( z_r \) is the residual impression depth, \( z_m \) is the maximum depth of penetration, and \( E \) is the numerical constant related to Poisson’s ratio and indenter’s geometrical factor. From Eq. (5) the extent of recovery depends on the \( H/E \) ratio. Thus, the ratio of \( H/E \) plays an important role in identifying the elastic/plastic behavior of materials.

When dealing with an elastic/plastic field in large scale events, where cracking occurs, \( H/E \) can be related to toughness. Lawn et al. [21] showed that the quantity \( E/H \) emerges as the primary manifestation of the elastic/plastic far-field driving force for fracture. The crack opening force, \( P_r \), produced by the residual stress field, can be expressed as \( P_r \sim (E/H)^{1/2} \cot \alpha c^3/2 \), where \( P_r \) is the peak indentation load, and \( \alpha \) is the semi-angle for an equivalent conical indenter. Assuming half-penny crack geometry, the stress intensity factor due to residual far-field force is written as \( K \sim f(\theta)P_r c^{3/2} \), where \( f(\theta) \) is an angular function introduced to allow for the effects of the free surface, and \( c \) is the crack length. Assuming that the crack arrests when it grows to a length at which the stress intensity factor is just equal to the fracture toughness [23]. An appropriate expression of fracture toughness, \( K_C \), evaluated by indentation testing can be written as

\[
K_C = k \left( \frac{E}{H} \right)^{1/2} \frac{P}{c^{3/2}}
\]

where \( k \) is an empirical constant that depends on the geometry of the indenter.

Because brittleness measures the relative susceptibility of a material to two competing mechanical responses, deformation and fracture, \( H/K_C \) has been proposed as the quantification of the brittleness [24] based on the critical flaw condition, \( C^* = \mu_1(K_C/H)^2 \), where \( \mu_1 \) is the geometrical constant. The inversion of brittleness is the ductility; therefore, \( K_C/H \), which is related to the allowable critical flaw size, represents the ductility index of materials in indentation testing.

In addition to the fracture mechanics analysis, an energy-based analysis is another approach that is used to determine elastic recovery, densification energy [25], and ductility [26] from load versus displacement curves obtained through indentation testing. Ductility is typically defined as the degree of plastic strain at fracture. The ductility index, \( D \), is defined in terms of the indentation energy ratio as follows [26]:

\[
D = \frac{E_I}{H_I}
\]

where \( E_I \) and \( H_I \) are the indentation modulus and hardness, respectively.
change in fracture toughness of the laser-irradiated zones. Five feed rate conditions at the same energy level, 30 \( \mu \)J, and another five laser pulse energy conditions at the same feed rate, 0.04 mm/s, were used to investigate the effects of laser pulse energy and laser scanning speed on feature morphology and mechanical properties due to structural modifications.

4 Results and Discussion

4.1 Experimental Morphology by Transmission DIC. As mentioned previously, when femtosecond laser pulses are focused through an objective lens to a spot inside bulk glasses, if proper conditions are met, the material confined within the focal volume experience structural modification. Usage of objectives with high NA (\( NA > 0.4 \)), feature morphologies appear to have shapes with smaller ratios of longitudinal to lateral radii \([5]\). This agrees well with the ratios of major to minor radii of an ellipsoidal focal volume as described by Zipfel et al. \([27]\). Using a three-dimensional Gaussian ellipsoid to approximate focal volume, the radii of focal volume at \( 1/e^2 \) intensity are \( NA \) dependent and written as \([27]\):

\[
\omega_x = \frac{0.32 \lambda}{NA} , \quad \omega_y = \frac{0.325 \lambda}{NA^{0.91}}, \quad \omega_z = \frac{0.532 \lambda}{n_1 - \sqrt{n_1^2 - NA^2}}
\]

where \( \omega_x \) and \( \omega_z \) represent the lateral and longitudinal radii of the Gaussian ellipsoid at \( 1/e^2 \) position in their corresponding direction, respectively, \( \lambda \) is the laser wavelength, and \( n_1 \) is the refractive index of the transparent material.

The cross sections of features created by different laser pulse energies with a scanning speed of 0.04 mm/s and by 30 \( \mu \)J laser pulses at various feed rates are seen clearly with the use of DIC optical microscopy, as shown in Figs. 2 and 3, respectively. These features have a long and narrow teardrop shape with an ellipsoidal dark core in the center. The shape and size of the core relates to the focal volume, as described by Eq. (8), and the distinctive color of this region could be a consequence of the high level of interaction of a material with laser pulses, which repeatedly deposit energy into this region with large overlap. The outer regions show some discoloration and are expected to have experienced a temperature equal or greater than the softening point of fused silica. The asymmetric shape of outer regions is considered to be the result of focusing effects \([16]\) and different temporal slices of the energy above the threshold \([1,5]\). The irregular profile near the top area of the features is probably caused by the inhomogeneous distribution of the laser intensity rather than material properties. Due to the nature of the process, the focal volume can be seen as heat source. This inner darker region can be associated with focal...
volume, where laser energy is directly deposited and the presence of the outer region is due to heat conduction between the focal volume and surrounding material [10,13,17]. From Figs. 2 and 3, it can be seen that the feature size is strongly dependent on the scanning speed and laser pulse energy. The higher laser pulse energies and lower feed rates correspond to formation of larger features. This is particularly important for transmission welding of the glasses in flat display industry where components inside of the enclosure can be thermally sensitive and highly localized weld is desired.

Figures 4 and 5 show the feature heights, widths, and aspect ratios (height/width) as a function of laser pulse energy and laser scanning speed, respectively. The feature heights and widths are, respectively, defined from the longest and the widest portions of both regular and irregular features. For higher laser pulse energies, the temperature in the focal volume is higher, and when it is conducted to the surrounding area, the affected region, which experiences the temperature above the softening point is bigger in both directions, as shown in Fig. 4. On the other hand, the higher the speed, the less time there is for heat to accumulate inside the focal volume. As a result, the temperature is lower, and the affected region is smaller both in height and width, as shown in Fig. 5. At the same laser scanning speed, 0.04 mm/s, the aspect ratios are more-or-less constant with the laser pulse energy in the range of the study, as shown in Fig. 4. This suggests that since each area of the material is processed for the same amount of time and there is no change in the focal volume ratio, the percentage of increasing size in each direction due to different pulse energies is about the same. However, from Fig. 5, the aspect ratios are decreased when the laser scanning speed is decreased, as similarly observed by Vukelic et al. [17]. Since the temperature gradients between the focal volume and the surrounding material in the axial and lateral directions are different due to the Gaussian ellipsoidal shape of the focal volume, heat flux will be greater and strongly conducts in the lateral direction. Thus, the percentage of increasing size in this direction is higher than another direction as a function of time, resulting in the decreased aspect ratios.

4.2 Morphology From Isotherm Modeling. As described in Sec. 4.1, heat accumulation and diffusion play an important role in feature formation. A simplified heat conduction model was used in order to capture the basic mechanisms of structure changes and to predict the size of the softening/melting region induced by femtosecond laser processing of transparent materials. The work piece material is assumed to be isotropic, and the temperature dependence of thermal conductivity and specific heat is taken into account. Modeling includes deposition of the femtosecond laser pulses at a 1 kHz repetition rate into the interior of a finite three-dimensional plate of fused silica. One-temperature heat conduction equation has been solved since the two-temperature model is suitable only for low fluences and widely used for metals [28]. The governing equation is therefore the temperature dependent classical heat equation with a laser source:

$$\rho C_p(T) \frac{\partial T}{\partial t} = \nabla (k(T) \nabla T) + I(x,y,z,t)$$

(9)

where $\rho$ is density, $C_p$ is specific heat, $k$ is conductivity, $x$, $y$, and $z$ are the Cartesian coordinates, $t$ is time, and $I$ is the laser intensity or the energy rate supplied externally into the body. Laser energy is assumed to be absorbed only inside a focal volume. Based on Eq. (8), the focal volume is modified to use a double ellipsoidal shape in order to compensate for a teardrop shape of features caused by focusing effects [16]. Therefore, the intensity profile of a moving laser beam is a 3D spatial Gaussian ellipsoid and a 1D Gaussian in time, which can be written as

$$I(x,y,z,t) = I_0 \exp\left(-\frac{2(\Delta x)^2 + (\Delta y)^2}{\omega_{xy}^2}\right) \exp\left(-\frac{2(\Delta z)^2}{\omega_z^2}\right) \times \exp\left(-4 \ln 2 \frac{t - 2t_p}{t_p}\right)$$

(10)

where $I_0$ is the peak intensity, $\Delta x$, $\Delta y$, and $\Delta z$ are distances measured in Cartesian coordinate system from the center of the laser beam, and $t_p$ is a full-width-at-half-maximum (FWHM) pulse width. The aspect ratio of the focal volume, $\omega_z/\omega_{xy}$, is kept con-

Fig. 3 Transmission DIC optical microscopy of cross section view (x-z plane) of femtosecond laser-irradiated fused silica (beam diameter of 1.5 $\mu$m, pulse energy of 30 $\mu$J, and rep rate of 1 kHz).

stant as it depends on wavelength and NA only, which are constant. Although simplified with respect to actual process, the established numerical model allows one to estimate the size of the affected region based on the input parameters, laser pulse energy, repetition rate and feedrate. The analysis is implemented with the commercial finite element method (FEM) program ABAQUS/STANDARD.

The representative isothermal contours of the affected region during processing using 30 μJ laser pulse energy and 0.04 mm/s laser scanning speed is illustrated in Fig. 6. The gray color contour represents the material region that experiences temperatures equal to or greater than the softening temperature of fused silica. This contour shape is similar to the feature morphology, as shown in Figs. 2 and 3. The feature sizes and aspect ratios of these numerical results along with the experimental ones are plotted as a function of laser pulse energy in Fig. 7. The numerical models predict the same increasing trend of feature size as the experimental results both in height and width, as shown in Fig. 7(a), and also the same more-or-less constant trend of the aspect ratios as the experimental ones, as shown in Fig. 7(b). However, there is some discrepancy between the numerical and experimental sizes. This is due to the fact that the numerical model does not take into account hydrodynamic motion and shock wave that comes as its consequence, as well as pressure effect. As a result, the size of the feature is underestimated. From Fig. 7(a), it is clearly seen that there is higher discrepancy in the prediction of the feature widths. Thus, it could be thought that the effects of shock wave and pressure are more dominant in determining the feature size in the lateral direction than in the axial direction. Subsequently, the aspect ratios are overestimated, as seen in Fig. 7(b). Therefore, the thermal model suggests that the mechanisms responsible for feature formation of femtosecond laser-irradiated fused silica using low repetition rate, high energy regime, and low scanning speed are more complex and could be the combinations of high pressure explosive plasma expansion and high temperature thermal diffusion. Future studies will concentrate on further improvement of the established numerical model.

4.3 Spatially Resolved Nanoindentation. An array of 200 nm depth nanoindentation measurements were performed over the cross section of femtosecond laser-modified fused silica with a spatial resolution of 5 μm, as shown by the reflection DIC optical micrograph in Fig. 8. The radius of plastic zone from a cavity model of an elastic-plastic indentation by a conical indenter, which described by Johnson [29], was used as a guideline to define the spacing between each indent. The plastically deformed radius is written as

\[ r_p = \frac{d}{\tan \beta} \left( \frac{E \tan \beta}{6Y(1-\nu)} + \frac{2-4\nu}{3-3\nu} \right)^{1/3} \]  

where \( r_p \) is the radius of plastic zone, \( d \) is the indentation depth, \( \beta \) is the angle between the indenter face and the surface (19.7 deg for the equivalent cone for a Berkovich indenter), \( E \) is Young’s modulus, \( Y \) is the yield stress, and \( \nu \) is Poisson’s ratio. The load-displacement curves of indents on both modified and unmodified regions in Fig. 8 were measured, and the representative curves of these two regions were compared, as illustrated in Fig. 9. Hardness and Young’s modulus are extracted from the loading and unloading curves, respectively.

The contour maps of two basic material properties, Young’s modulus and hardness, correspond to the array of nanoindentors in the optical micrograph were plotted, as shown in Fig. 10. It is observed that Young’s modulus and hardness in the femtosecond laser-irradiated region are reduced, and that the size and shape of these contours look similar to the morphology of the affected region in Fig. 8. The reduction in modulus and hardness confirms the presence of structural modifications inside the affected region. The region undergoes irreversible densification, which is a consequence of high pressures created by the plasma expansion. At the same time, the presence of breaks in the linkage within a structure due to the nature of the process also allows easier displacement of the atoms and reduces the elastic modulus [30]. Young’s modulus should be proportional to the number of bridging bonds per unit volume of glass [31], and the hardness relates to the connectivity of the structure [32]. From fluorescence microscopy it was shown that, in fused silica, nonbridging oxygen hole centers (NBOHCs) are formed in the regions exposed to femtosecond laser irradiation, especially in high pulse energy regime [14]. NBOHCs are considered as defects and cause the connectivity of glass network.
structure to be decreased. Therefore, the combination of high pressure and high temperature generated by femtosecond laser pulse trains cause the material in the affected region to become more flexible and softer. As the point that has the lowest value of Young’s modulus and hardness shown in Fig. 10 is aligned with the optical axis of laser pulses and is almost in the middle of the feature, it could be the center of the intensive interaction region as discussed in Sec. 4.1, and the existence of this weakest point is a consequence of that.

Figure 11 shows the spatially resolved mapping of $H/E$ ratios over the femtosecond laser-irradiated region. It is observed that the $H/E$ ratios in the femtosecond laser-irradiated region are reduced. When focusing on elastic and plastic strains and considering each of the two properties, Young’s modulus and hardness, materials with lower values of Young’s modulus exhibit lower resistance to elastic deformation or higher elastic strain, while materials with lower values of hardness exhibit lower resistance to plastic deformation or higher plastic strain. However, in displacement-controlled nanoindentation, there is the same amount of total strain, and the elastic and plastic strain portions cannot increase or decrease at the same time. Thus, the changes of these two properties will compete with each other, and the materials will show their changes in elastic/plastic behavior. Plastic behavior dominates at lower values of $H/E$, while elastic behavior dominates at higher values of $H/E$. Therefore, the decrease in $H/E$ ratios means the material in the modified region experiences a higher degree of plastic deformation, which can be viewed as an increase in ductility.

Furthermore, one can determine the ductility index through employment of Eq. (7). The ratio of the irreversible hysteresis loop energy $U_r$ to the total energy, $U_t$, is defined as the degree of plastic flow. The ductility index $D$ varies from 0.0 for a purely elastic to 1.0 for a purely plastic material. A mapping of the results from this approach is illustrated in Fig. 12. The contour map

![Graph showing experimental and numerical feature morphology comparison](image1)

![Graph showing spatially resolved nanoindentation array](image2)

![Graph showing representative load-displacement curves](image3)
showed that the ductility index of femtosecond laser-irradiated region is increased up to 25%. The increase in ductility index corresponds well with the highly plastic behavior indicated by the decrease in $H/E$ ratio.

With the “open” network structure of fused silica, it is considered that the main mechanism for plastic deformation is densification rather than plastic flow [33] and that the irreversible hysteresis loop energy $U_r$ can also be defined as the energy consumed for densification [25]. The increase in normalized irreversible loop energy shown in Fig. 12 corresponds to the increase in refractive index of the treated glass [13]. Spatially resolved and decomposed Raman spectral analysis [17] revealed that the volume fraction of three- and fourfold rings of affected regions irradiated by 30 $\mu$J pulse energy and 0.04 mm/s scanning speed increases as illustrated in the contour map of Fig. 13. The densification has been related to the change of structure from five- and sixfold rings to become three- and fourfold rings, which have smaller intertetrahedral angles and thus are more densely packed. Therefore, in addition to the increase in refractive index [13,14], as well as the structural changes characterized by spatially resolved Raman spectroscopy [17], the increase in normalized dissipated energy by spatially resolved nanoindentation testing also suggested that fused silica irradiated by femtosecond laser pulses undergoes densification.

Toughness, a measure of the ability of a material to absorb energy up to fracture, is an integration product of strength and degree of plastic strain or ductility. Considering the conservation of the volume in the cavity model, Johnson [29] located the elastic-plastic boundary for conical or pyramidal indenters during contact. The expression, which relates hardness, $H$, to yield strength, $Y$, and Young’s modulus, $E$, is written as
Fig. 13 Volume fraction distribution of three- and fourfold ring structures based on the 606 cm\(^{-1}\) and 495 cm\(^{-1}\) peaks in Raman spectra of cross section of femtosecond laser-irradiated region (30 \(\mu\)J pulse energy and 0.04 mm/s scanning speed) [17]

\[
\frac{H}{Y} = \frac{2}{3} \left[ 1 + \ln \left( \frac{E \tan \beta}{6(1-\nu)Y} + \frac{2(1-2\nu)}{3(1-\nu)} \right) \right]
\]

where \(\beta\) is the angle between the indenter face and the surface, and \(\nu\) is Poisson’s ratio. As can be seen from this equation, when \(H/E\) is decreased, the yield strength is also decreased. Femtosecond laser-irradiated regions showed a decrease in yield strength and an increase in ductility. Thus, the changes in toughness result from the competitions between the percentage decrease in yield strength and the percentage increase in ductility. If the change in yield strength was less dominant, the affected regions of fused silica would have higher toughness.

4.4 Effect of Laser Processing Parameters on Mechanical Responses. As demonstrated previously, the materials in the affected region are more flexible (lower \(E\)), softer (lower \(H\)), and highly plastic (lower \(H/E\) ratio). Referring to the difference of each property between the untreated and the irradiated regions, Figs. 14 and 15 show the maximum decrease of modulus, \(E\), hardness to modulus ratio, \(H/E\), and hardness, \(H\), as a function of laser pulse energy and laser scanning speed, respectively. All three quantities show decreasing trends in cases of increasing pulse energy or decreasing scanning speed. The decreasing trend of the \(H/E\) ratios revealed more dominant plastic behavior in the new structural materials created by more energetic pulses or by slower scanning speeds. Due to higher pressures and temperatures caused by more energetic pulses, the mean separation between the atoms increases, and the structure of the irradiated glass tends to exhibit more breaks in the linkage. Thus, the more NBOHCs are created, and the connectivity of the structure decreases. Therefore, \(E\) and \(H\) decrease further with an increase in laser pulse energy. On the other hand, the lower the speed, the more interaction time and a higher number of pulses are used to modify the network structure of the glass. As a result, there are more NBOHCs, and the connectivity of the structure decreases. Therefore, there is a further decrease in \(E\) and \(H\) due to the decrease in laser scanning speed.

4.5 Fracture Toughness Comparison. Cracks were produced in the glass using 2 \(\mu\)m depth displacement-controlled and 440 mN load-controlled nanoindentation tests. Due to the feature size and the residual imprint size, only one or two indents could be placed on each feature as shown by the reflection DIC optical micrograph in Fig. 16. After indentation, the fused silica samples were scanned by AFM to investigate and measure the final crack lengths, \(c\), from the center of the residual impression to the ends of cracks at specimen surface, as shown in Fig. 17. The decrease in \(H/E\) ratios of the affected regions, as shown in Sec. 4.3, which represents highly plastic behavior, will cause the larger impression lengths, \(a\), measured from the center of the contact to the corners of the impression. As expected, the final crack lengths, \(c\), which should have a direct relationship with the impression lengths, were larger in the affected regions that were created by both load- and displacement-controlled nanoindentations.

From the final crack length, \(c\), max load, \(P\), and the \(E/H\) ratio, the fracture toughness, \(K_{IC}\), in the femtosecond laser-irradiated regions was calculated as a function of laser pulse energy and laser scanning speed and compared with the values from the untreated regions, as shown in Fig. 18. Although the higher \(E/H\) ratios of the modified materials enhance the residual forces, which drive the crack, the power of the \(E/H\) term is three times less than that of the \(c\) term in Eq. (5). Thus, the fracture toughness is de-
increased compared to the untreated regions. However, the brittleness index $H/K_C$ in the affected region is decreased as well, which corresponds to the increase in ductility index. As shown previously in Figs. 14 and 15, the $H/E$ ratios were more reduced in cases of increased laser pulse energy and decreased laser scanning speed. The increase in $E/H$ ratios and the larger crack lengths, $c$, in cases of increasing pulse energy or decreasing scanning speed, cause decreasing trends of fracture toughness, as shown in Fig. 18. It is shown that the maximum decrease is less than 10%, and the decrease in fracture toughness can be minimized if lowering the pulse energies or increasing the scanning speeds.

5 Conclusion

The interior of fused silica was irradiated by femtosecond laser pulses with pulse energies higher than the threshold for multiphoton and avalanche ionization. The morphology of the affected regions has been investigated, and it has been observed that the feature size increased in both height and width with an increase of the laser pulse energy or with decrease of the scanning speed. The aspect ratios remain more-or-less constant with pulse energy due to the constant size of focal volume and constant interaction time. Furthermore, an increase with scanning speed is due to reduced interaction time and the preferable direction of heat conduction caused by the differences in temperature gradients between the radial and longitudinal directions. Spatially resolved measurements of mechanical properties, i.e., hardness, Young’s modulus, and $H/E$ ratios, on cross sections of the affected regions were performed. Decreases in Young’s modulus and hardness were observed due to higher content of the NBOHCs in treated regions that cause lower connectivity of the atomic structure caused by energetic pulse interaction with the material. However, the new structural material exhibits greater plastic behavior, and the ductility increases. This study has also shown that the fracture toughness is slightly decreased (<10%) and the processing conditions of this study could be used for transmission welding applications.

Furthermore, this study has shown that the decrease in fracture toughness can be minimized by lowering the laser pulse energy or increasing the laser scanning speed.
